### Biography

**Dr Chris Turner** graduated from the University of Oxford Medical School in 1996 with the *Sir George Pickering Prize* for top of year. He then undertook medical house physician jobs in the Nuffield Department of Medicine in Oxford and subsequently trained at the Hammersmith Hospital and Queen Square. With a growing interest in degenerative mechanisms in the nervous system he undertook a PhD with Professor Tony Schapira at the Institute of Neurology, Royal Free campus, London into the “Molecular Pathogenesis of Huntington’s Disease.” His specialist neurology training was conducted at Queen Square, Chelsea and Westminster and St George’s Hospitals after which he took a Consultant Neurologist position in 2007 in the MRC Department for Neuromuscular Disease at Queen Square. He has developed a specialist interest in the Myotonic Dystrophies since his appointment and has spoken at national meetings of the MDSG as well as on lecture courses. He is currently involved in developing a National UK Myotonic Dystrophy Registry and Standards of Care for DM. He runs the Myotonic Dystrophy clinic at Queen Square.

## Hereditary and Autoimmune Myasthenias

David Beeson

Nuffield Department of Clinical Neuroscience, University of Oxford, Oxford, UK

This article is a revision of the previous edition article by David Beeson and Nicholas Willcox, volume 3, pp 3072–3087.

### 131.1 INTRODUCTION

Myasthenia gravis (MG) and allied disorders of neuromuscular transmission are uncommon. They are characterized by weakness of voluntary muscle that is usually fatigable and often affects the extraocular and eyelid muscles at an early stage. Here, they are considered in order after a brief introduction to neuromuscular physiology.

### 131.2 NORMAL NEUROMUSCULAR TRANSMISSION

Motor nerve fibers are ensheathed by Schwann cells almost as far as the neuromuscular synapse, where they expand to form the nerve terminals, which are rich in both mitochondria and synaptic vesicles containing acetylcholine (ACh) (reviewed in Reference (1)). The nearby muscle membrane is highly folded and the ACh receptors (AChRs) are densely packed on the crests of these folds (Figure 131-1) (2). By contrast, the ACh esterase (AChE) is diffusely attached to the basal lamina throughout the intervening space, extending down into the clefts between the folds. The molecular anatomy and development of this exceptionally well-studied synapse are elegantly reviewed by Sanes and Lichtman (3), and its physiology by Vincent and Wray (4).

The vesicles can discharge spontaneously by fusing with the membrane, each releasing 5000 to 10,000 molecules of ACh. About 6000 of these bind to the AChRs and open their intrinsic cation channels, thus depolarizing the membrane locally; each resulting miniature endplate potential (mepp) is 0.8–1.0 mV in amplitude. By contrast, when a nerve impulse reaches the terminal, it causes voltage-gated calcium channels (VGCC), located in active zones in the nerve membrane, to open, and the resulting entry of  $\text{Ca}^{2+}$  ions triggers the discharge of about 50 vesicles. As the ensuing mepps summate, the endplate potential (epp) reaches threshold, and an action potential

is propagated in the muscle membrane by voltage-gated sodium channels. These are concentrated in the synaptic clefts but extend over the entire muscle fiber, so that the action potential spreads, ultimately triggering a contraction. After breakdown of ACh by AChE, residual choline is taken back into the nerve terminal and reincorporated into ACh by the enzyme choline acetyltransferase. The vesicles themselves are initially synthesized in the motor nerve cell body and transported down the axons to the synapse, where they are repeatedly recycled.

Normally, in humans, a nerve impulse depolarizes the muscle membrane from about  $-70$  mV to about  $-40$  mV, which only modestly exceeds the threshold of  $-50$  mV (Figure 131-1). This roughly 10 mV difference (the safety factor of transmission) is much smaller in humans than in some other species (e.g. mouse). The loss of this safety factor is fundamental to almost all the myasthenias and may result from an impaired transmitter release, a decrease in receptor numbers, altered receptor function, or altered synaptic structure (1).

### 131.3 DIAGNOSTIC METHODS

Standard electromyography (EMG) can readily detect both the impaired transmission and especially its partial recovery after maximal voluntary contraction (post-tetanic potentiation) that is characteristic of some presynaptic defects. Similarly, it may show the fatiguing decline in responses to repetitive stimulation (at 3 Hz)—“decrement”—typical of postsynaptic disorders, and single-fiber EMG may also reveal asynchronous responses of muscle fibers supplied by branches of the same axon—“jitter” (reviewed by Harper (5)). In specialist centers, electrophysiological studies of single endplates from biopsied muscle can quantify the number of packages of ACh released after a single impulse (“quantal content”), and so confirm a presynaptic disorder as in the Lambert–Eaton myasthenic syndrome (LEMS).

**FIGURE 131-1** The neuromuscular junction. Action potentials are propagated in the axon membrane by voltage-gated  $\text{Na}^+$  channels (and are terminated partly by the action of voltage-gated  $\text{K}^+$  channels). When they reach the nerve terminal, they open voltage-gated  $\text{Ca}^{2+}$  channels in the active zones (triangles). The resulting  $\text{Ca}^{2+}$  entry causes synaptic vesicles to discharge their ACh toward the crests of the folds in the muscle membrane opposite, where the AChRs are very densely packed (ovals). Voltage-gated sodium channels (squares) are activated once the membrane depolarization rises above  $-50\text{mV}$ .

The amplitudes of the mepps and epps, and their rise and decay times may suggest abnormalities in the numbers or kinetics of the AChRs (6). Straightforward staining for AChE gives an estimate of the endplate morphology and length (normally up to 8 sarcomeres) as well as of the AChE content (7). Binding of iodinated  $\alpha$ -neurotoxins (e.g.  $\alpha$ -bungarotoxin [ $^{125}\text{I}$ - $\alpha$ -BuTx]) quantifies any deficiency in AChR; normally in intercostal muscle, there are about  $1.2 \times 10^7$  binding sites per endplate (8). More specialized electron microscopy may also be invaluable (1). Once an initial diagnosis is made, genetic analysis has now become the gold standard for confirmation of an hereditary disorder.

If autoimmune MG is suspected, there is a highly sensitive and specific antibody assay that uses human muscle AChR prelabeled with  $^{125}\text{I}$ - $\alpha$ -BuTx, and gives positive results in more than 85% of patients with MG (9,10); another 5–10% instead have antibodies against muscle-specific tyrosine kinase (MuSK), which can be measured similarly (11). There are now equally valuable assays for antibodies to calcium channels for the LEMS (12). Finally, measurable clinical improvement up to 3 weeks after a course of plasma exchange may be an invaluable clue to an autoantibody-dependent pathogenesis (13).

### 131.4 ACETYLCHOLINE RECEPTOR

In the midterm fetus, the nicotinic AChR consists of  $\alpha_2$ ,  $\beta$ ,  $\gamma$ , and  $\delta$  subunits (Figure 131-2B), but, in the last trimester, an  $\epsilon$  gradually replaces the  $\gamma$ . These two AChR isoforms differ both antigenically and in their channel kinetics. The subunits are all evolutionarily related and comprise 437 to 496 amino acids (summarized in Reference (14)). Each has about 210 amino acids of

**FIGURE 131-2** The acetylcholine receptor, viewed (A) from the side, (B) from the nerve terminal, illustrating the two isoforms of the AChR. (C) Topography of the  $\alpha$ -subunit.

extracellular sequence, three highly conserved transmembrane segments (M1–M3) almost in tandem, a more variable cytoplasmic loop, a fourth transmembrane segment, and a short extracellular tail (see Figure 131-2C). Together, they form a cylindrical structure (see Figure 131-2A) with the M2 segments of each subunit lining the central cation channel; charged residues forming a “funnel” at each end are thought to control its ion selectivity and conductance. The preference for  $\text{Na}^+$  is relative; about 6% of the normal current is due to  $\text{Ca}^{2+}$  entry. The M2 segments form amphipathic  $\alpha$  helices/ $\beta$  strands with (roughly) alternating hydrophobic and polar residues. At rest, the channel lumen is occluded by amino acid side-chains in the M2 segments of several subunits (15–17). These shift during the conformational change that follows ACh binding to sites at both the  $\alpha/\delta$  and  $\alpha/\epsilon$  (or  $\alpha/\gamma$ ) interfaces (18). This allows cations (mainly  $\text{Na}^+$ ) to enter the muscle and depolarize its membrane.

At the neuromuscular junction there are many potential target sites for genetic defects or for attack by autoantibodies or neurotoxins. They include the ion channels in the axons, nerve terminals and muscle membrane, the synthesis and recycling of the synaptic vesicles, the AChE and AChR molecules, and the numerous other molecules involved in their localization to the endplates, their anchorage there or in the synaptic structure itself (19). In particular, evidence from experiments in mice in which components of the neuromuscular junction were “knocked out” suggests that a core pathway is responsible for initiating and maintaining the specialized postsynaptic structures at the neuromuscular junction. In this pathway, agrin, released from the nerve terminal, activates MuSK located in the postsynaptic membrane; the MuSK signal is amplified through interaction with Dok-7 (20) and this leads to the precise aggregation and localization of the AChR through the association with the cytoplasmic anchoring protein rapsyn (3). Disruption of this core pathway is likely to result in a myasthenia (21).

### 131.5 CONGENITAL MYASTHENIC SYNDROMES

The “congenital” myasthenic syndromes (CMSs) are inherited disorders of neuromuscular transmission with no underlying autoimmune basis; they are reviewed by Engel and associates (6). They are heterogeneous, reflecting the diversity of underlying genetic defects, but share the characteristic fatigable muscle weakness with autoimmune MG. CMSs account for only around 5% of all myasthenias, but this number is increasing with improved diagnosis. Despite their name, in some syndromes there is great variation in the age of onset, with some not presenting until childhood or even after puberty. If neonates are affected, they typically show weakness on sustained exertion, for example, during crying and feeding, reflecting bulbar involvement. More seriously, there may be difficulties in respiration, requiring resuscitation. Any subsequent apneic attacks demand urgent therapy or even ventilation, both of which the parents must be trained to administer. If these measures are successful, the patients usually stabilize with therapy and they develop remarkably well in spite of some disability (22).

The phenotypes of the various CMSs are often superficially similar. Clinical, electrophysiological, cytochemical and morphological analysis has helped to discriminate postsynaptic, synaptic or presynaptic defects (reviewed in References (1) and (23)). The molecular genetic bases for many postsynaptic and synaptic syndromes (reviewed in Reference (6)) are now well understood and should help to improve their classification; however, other examples do not yet fall clearly into the categories listed in Table 131-1. Before describing these disorders, we now list some general conclusions.

First, AChR loss is a major cause of CMS. Second, apart from the slow-channel syndrome (see later), all the CMSs show recessive inheritance; many result from compound heterozygosity with distinct mutations in each allele (heteroallelism) or from parental consanguinity. Third, different molecular mechanisms can generate surprisingly similar syndromes from mutations in diverse regions of the AChR, Rapsyn, ChAT, ColQ or Dok-7. Fourth, different families with the same mutation can show remarkable differences in severity, implying other modifying influences; their identification might be turned to therapeutic advantage in the future. Fifth, the majority of known mutations in the AChR are in the adult-specific  $\epsilon$  subunit; presumably many patients survive through persistent low-level fetal ( $\gamma$ ) subunit expression that may vary between patients, whereas homozygosity for null alleles of other subunits might be lethal in utero. Sixth, the pathogenicity of many CMS mutations has been confirmed by comparing mutant protein function in transfected cells (biochemically or electrophysiologically) with that in patient muscle biopsies. Finally,

**TABLE 131-1 Major Categories of Congenital Myasthenias**

Classification of congenital myasthenic syndromes (CMS) and their genetic loci*	
Presynaptic CMS	Gene
CMS with episodic apnea	<i>CHAT</i>
Synaptic CMS	
Congenital endplate acetylcholinesterase deficiency	<i>COLQ</i>
CMS due to mutations in Agrin	<i>AGRN</i>
CMS due to mutations in the laminin $\beta 2$ chain	<i>LAMB2</i>
Postsynaptic CMS

functional analysis of the mutated proteins is often required to determine pathogenicity for the many variants that are found in genes encoding neuromuscular junction proteins.

#### 131.5.1 Postsynaptic Defects

Mutations within the genes encoding the AChR or the AChR clustering proteins rapsyn and Dok-7 are the major cause of these abnormalities, although kinships with mutations in MuSK (24), Agrin (25) and the postsynaptic voltage-gated sodium channel have also been reported (26). More recently a CMS due to mutations in the ubiquitously expressed GFAT1 (*GFPT1* gene) has been identified (27), and it is not yet certain in these cases whether the primary defect is pre- or post-synaptic. The AChR subunits are encoded by separate genes of 10–12 exons; the *CHRNA*, *CHRNA* and *CHRND* loci (for  $\alpha$ ,  $\gamma$  and  $\delta$ ) are on chromosome 2, the *CHRNB*, and *CHRNE* ( $\beta$  and  $\epsilon$ ) loci are on chromosome 17 (14,28) and the *RAPSN* locus is on chromosome 11 (29). The various mutations may either increase or decrease the synaptic response to ACh; the clinical syndromes fall into five main groups, although rarely mutations are identified in other

neuromuscular junction proteins. Some of the mutations that cause AChR deficiency due to mutations in *CHRNAE* or *RAPSN* are illustrated in [Figure 131-3](#), although a more extensive table is listed in Reference (30).

### 131.5.2 Acetylcholine Receptor Deficiencies

AChR deficiency may arise from mutations within the AChR itself or through mutations in the clustering protein rapsyn. Currently, these are not distinguishable by EMG or muscle biopsies, but careful examination of the differing clinical features may help to predict the affected gene. The majority of AChR mutations causing AChR deficiency are located in *CHRNE* ( $\epsilon$  subunit), but rare severe examples have been identified in *CHRNA*, *CHRNA*, and *CHRNA* ( $\alpha$ ,  $\beta$  and  $\delta$  subunits).

### 131.5.2.1 AChR Deficiency due to Mutations in the AChR $\epsilon$ -Subunit.

**131.5.2.1.1 Clinical Features.** There is a characteristic reduction in endplate AChR numbers that results in reduced responses to ACh. These recessive disorders are the most common CMSs in the United Kingdom. Weakness is usually evident at birth or in the first few years of life and is characterized by feeding difficulties, ptosis, impaired eye movements, and delayed motor milestones. Ophthalmoplegia is a prominent and early feature that may help in differential diagnosis. Specialized EMG shows reductions in mEPSP amplitudes and, sometimes, a supranormal evoked quantal ACh release. Morphologically, the endplates are elongated with patchy endplate staining and simplified postsynaptic membrane folding (6). There is usually a good response to anticholinesterase medication; 3,4-diaminopyridine, which enhances ACh release, may be a useful alternative (31), but is available only from specialist centers.

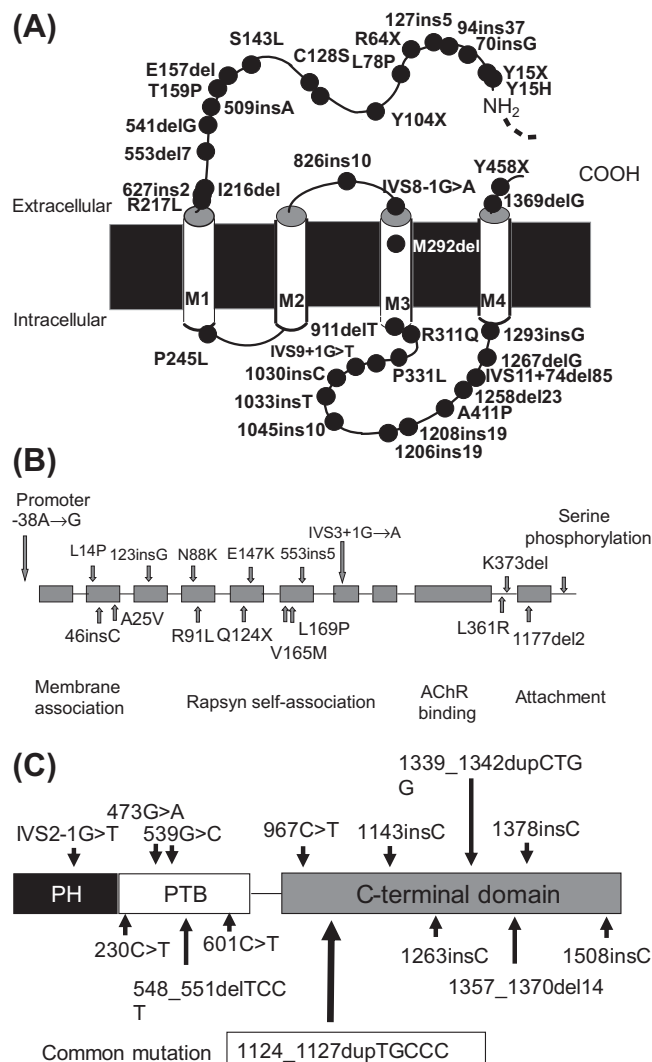

**131.5.2.1.2 Molecular Basis.** The vast majority of mutations within the AChR that cause an AChR deficiency syndrome are located in the  $\epsilon$ -subunit gene. More than 100 different mutations have been identified (6), and typical examples are shown in Figure 131-3A. In the UK there are few obvious founder effects, although  $\epsilon$ 1267delG is a common mutation in patients of gypsy ethnic origin (32), and  $\epsilon$ 1293insG in cases from north Africa (33). Several types of mutation have been identified along the gene (see Figure 131-3A);

- (i) promoter mutations affecting transcription (34);
- (ii) premature termination of the translated chain caused by frameshift, intron splice site or nonsense mutations (6);
- (iii) missense mutations in residues essential for folding/assembly, for example, in leader sequence, glycosylation site or cysteine loop (see Figure 131-3A) (6).

It has been shown that the presence of a cysteine residue three amino acids from the  $\epsilon$ -subunit C-terminus is required for surface expression and thus almost all mutations causing truncations will give rise to null alleles (35). In these cases, the residual neuromuscular transmission probably depends on low levels of the fetal form of the AChR ( $\alpha_2\beta\gamma\delta$ ).

### 131.5.2.2 AChR Deficiency due to Mutations in Rapsyn.

**131.5.2.2.1 Clinical Features.** The disorder may be divided into a more common “early-onset” phenotype that presents at birth or in early childhood and a “late-onset” phenotype that may present from early adulthood through to late middle age. By contrast with patients harboring  $\epsilon$ -subunit mutations, ophthalmoplegia is rarely seen in patients with rapsyn mutations, although they appear to have a high prevalence of strabismus. The early-onset phenotype usually presents at birth with hypotonia and bulbar dysfunction, and the patient may require assisted ventilation. Mild fixed joint

**FIGURE 131-3** Topological or linear representation for example mutations in the three most common forms of congenital myasthenic syndrome. (A) AChR deficiency syndrome mutations in the  $\epsilon$  subunit. (B) Rapsyn functional domains and the position of some of the identified mutations. (C) Dok-7 functional domains and positions of some of the identified mutations.

contractures (arthrogryposis multiplex congenita) of hands and ankles is a characteristic and frequent feature. Typically, there are severe exacerbations during early childhood, often presenting with respiratory failure, and often associated with minor infections; these usually resolve around the age of 6 years. Symptoms improve later in life, and the majority of patients experience little disability in adulthood. Similar episodic exacerbations have been described in CMS with episodic apnea, a much rarer disorder, caused by mutations in genes encoding presynaptic choline acetyltransferase and in fast channel syndromes (see later). The late-onset phenotype often follows a mild benign or episodic course and can easily be mistaken for seronegative immune-mediated MG or indeed not recognized at all. Patients frequently show marked weakness of ankle dorsiflexion (unusual in MG) in addition to proximal limb weakness. The majority of patients with rapsyn mutations (both early- and late-onset) respond extremely well to anticholinesterase medication, although some gain further benefit from the addition of 3,4-diaminopyridine. By contrast, even with the combination of anticholinesterase medication and 3,4-diaminopyridine, many patients with AChR- $\epsilon$  mutations remain moderately impaired (36,37).

**131.5.2.2 Molecular Basis.** By contrast with AChR deficiency due to AChR- $\epsilon$  mutations, nearly all rapsyn patients share the common missense mutation N88K (36). This greatly facilitates the genetic screen for this disorder. N88K is present in both Indian and European populations, and is thought to be derived from the same ancient founder (38). Patients may be homozygous for N88K or compound heterozygotes for N88K and a second mutated allele. A series of mutations have now been identified at the RAPSN gene locus (Figure 131-3B) (36,37). The precise mechanism through which each mutation caused the reduced number of AChR in the postsynaptic membrane has not been clearly defined, but it may involve the interaction of the AChR with rapsyn, the ability of rapsyn to self-cluster, and the stability of the rapsyn or the rapsyn-AChR clusters. In addition to mutations within the coding sequence, mutations have also been detected in the promoter region of the gene, and in particular  $-38A>G$  was observed at homozygosity and shown to arise from a common founder in near eastern Jews. Affected individuals with  $-38A>G$  show marked jaw and other facial malformations (39). The promoter mutations severely reduce the level of rapsyn mRNA transcription and may be found in the absence of N88K (39).

### 131.5.3 Fast-Channel Syndromes

**131.5.3.1 Clinical Features.** These recessive defects in the response to ACh are due to kinetic abnormalities of AChR function. Although the ultrastructure usually appears relatively normal, there may also be some reduction in endplate AChR numbers. Phenotype

may vary along with the particular molecular effects of the mutations, but these disorders may be severely disabling. Typically the patients present at birth with respiratory and/or bulbar problems, ophthalmoplegia and generalized muscle weakness. As is the case for RAPSN and CHAT mutations, apneic episodes are common in early life. In general they show a dramatic initial response to cholinesterase inhibitors but over time the benefit gradually reduces, and the addition of 3,4-diaminopyridine (3,4-DAP) is usually required.

**131.5.3.2 Molecular Basis.** The first defined examples were in compound heterozygotes with one low-expressor allele (40). In the other allele, an  $\epsilon$ L121P mutation caused reduced affinity for ACh and abnormally brief channel opening events. These kinetic effects were unmasked because of the concomitant null ( $\epsilon$ S143L) or low expressor ( $\epsilon$ G-8R) alleles (see iii earlier and Figure 131-3A). Other described fast-channel mutations are  $\alpha$ V132L,  $\delta$ E57K,  $\epsilon$ N182Y, and  $\epsilon$ D175N (41–43) and require the presence of a second null or low expressor mutation to unmask the fast channel phenotype (although  $\epsilon$ N182Y and  $\epsilon$ D175N were identified as heteroallelic in one patient; 42). A single example of dominant inheritance of a fast-channel syndrome caused by mutation  $\alpha$ F256L has been reported (44).

### 131.5.4 Slow-Channel Syndromes

**131.5.4.1 Clinical Features.** Usually, this disorder shows dominant inheritance. Age at onset and severity are strikingly variable, some carriers appearing unaffected. Most patients show selective severe involvement of wrist and finger extensor muscles. Frequently, there is a repetitive response to a single nerve stimulus and mepps and mep currents are prolonged. On microscopy, there is usually type I fiber predominance, and electron microscopy shows degenerative changes, sometimes with tubular aggregates that are termed an “endplate myopathy.” This also involves widening of the synaptic cleft, degeneration of the junctional folds, the subsynaptic mitochondria and nuclei, and vacuole formation. Unlike AChR deficiency and the fast-channel syndrome, this disorder is slowly progressive and anticholinesterase treatment or 3,4-diaminopyridine are ineffective or may even make the condition worse. Quinidine sulfate (serum levels of 0.7–2.5  $\mu$ g/mL) and fluoxetine, which both act to block the AChR ion channel when it is in the open state, are beneficial, although dose-related side effects may occur for both (45,46).

**131.5.4.2 Molecular Basis.** The slow-channel syndrome is caused by prolonged AChR channel activations. More than 18 different mutations have been reported (6). They occur not only in different subunits but also in different functional domains within them. They are all single amino acid changes and lead to a pathogenic gain of function in the AChR that explains their dominance. Mutations located in the M2 transmembrane segment

are thought to act predominantly by slowing channel closure (6). Others enhance the affinity of the AChR for ACh, which results in repeated openings of the channel during an extended period of ACh occupancy (47). These prolong the epp, causing the repetitive responses to single nerve stimuli. The pathogenicity of some of these mutations has been confirmed in transgenic mouse models (48).

Whatever the exact mechanisms, the prolonged openings apparently cause chronic, excessive entry of calcium ions through the open AChR channels resulting in an endplate myopathy. The myopathy may be exacerbated by activation of mutant channels by free local choline (49). In addition to this excitotoxic effect, persistent depolarization, resulting from summation of the prolonged endplate potentials, may cause muscle dysfunction at physiological rates of stimulation.

### 131.5.5 The Dok-7 Neuromuscular Junction Synaptopathy

**131.5.5.1 Clinical Features.** Dok-7 is a crucial molecule involved in the pathway that both clusters the AChR on the crests of the postsynaptic folds and also maintains the synaptic structure. Disorders resulting from mutations within Dok-7 are recessive (50). Age of onset varies, and some respiratory problems and stridor have been reported at birth or in early infancy (51). More commonly early motor milestones are normal and symptoms first present between 18 and 36 months with frequent falls. Thus, clinical onset is usually characterized by difficulty in walking after normal initial walking milestones. Ptosis may sometimes be present at birth but more usually develops in childhood. In general, proximal muscles are more affected than distal ones, leading to a typical “limb girdle” pattern of weakness, and, although ptosis was often present, extraocular muscles were rarely involved. Fluctuation in symptoms is common and patients may have been previously diagnosed with an unspecified congenital myopathy (52). There is a remarkable variation in disease severity with symptom onset ranging from birth to adolescence, or even into adulthood. Patients do not show long-term benefit from anticholinesterase medication and sometimes worsen; however, these patients generally show a remarkable improvement with ephedrine or salbutamol. The effect of these drugs is not seen immediately but rather there is a gradual but dramatic improvement over a period of months, and patients continue to improve for up to a year before the effect plateaus (53).

**131.5.5.2 Molecular Basis.** As is evident from the name, this disorder results from mutations in the adaptor protein, Dok-7. Dok-7 binds to the phosphotyrosine-binding site on MuSK located close to the postsynaptic membrane (20) and is thought to amplify the signal that results from Agrin binding. Mutations are located along the length of the Dok-7 protein. Surprisingly, Dok-7

polypeptides that are truncated in the C-terminal region remain partially active, and thus many of the mutations, including frame-shifting insertions or deletions are located in this region. This includes a common mutation c.1124\_1127dupTGCC that is found in around 60% of UK patients with Dok-7 mutations (50,52,54,55). In vitro cell culture experiments show that the Dok-7 mutations cause reduced agrin-induced AChR clusters, and that the form of these clusters is less complex, suggesting that Dok-7 is involved both in the maturation and maintenance of the neuromuscular junction structure.

### 131.5.6 Limb-Girdle CMS due to *GFPT1* Mutations

**131.5.6.1 Clinical Features.** These include fatigable weakness of the shoulder and hip girdle muscles, normal eye movements and minimal facial weakness, good response to esterase inhibitors, and evidence of tubular aggregates on muscle biopsy. As with most congenital myasthenic syndromes there is variability in severity, but in general onset is in childhood, usually slightly later than is seen for Dok-7 congenital myasthenic syndrome, and there is a deterioration in the strength of limb-girdle muscles over the following few years that limits sustained walking (27,52).

**131.5.6.2 Molecular Basis.** Classical linkage analysis and positional cloning have identified mutations in *GFPT1* to account for many of the cases of limb-girdle CMS associated with tubular aggregates on biopsy. Screening for *GFPT1* mutations in unsolved CMS cases with a wide range of different clinical phenotypes, but without tubular aggregates, was negative confirming that *GFPT1* mutations are associated with a distinct and recognizable CMS phenotype. *GFPT1* encodes the enzyme glutamine:fructose-6-phosphate amidotransferase 1, a key enzyme of the hexosamine biosynthetic pathway which yields the amino sugar UDP-N-acetylglucosamine (UDP-GlcNAc), which is an essential substrate for protein glycosylation. Thus, it may be that the glycosylation of components at the neuromuscular junction are impaired in this disorder (27).

### 131.5.7 Other Postsynaptic Syndromes

It seems probable that mutations in other key proteins involved in neuromuscular transmission will underlie additional CMSs (21). Examples described include reports of patients heteroallelic for mutations in MuSK (56), the postsynaptic voltage-gated sodium channel, *SCN4A* gene (26), or Agrin which stabilizes clustered AChR at the endplates (25). The patient with MuSK mutations had a fluctuating course of disease with episodes of severe respiratory distress in early childhood. Muscle biopsy revealed reduced endplate AChR levels; there was no clinical benefit from anticholinesterase medication on its own, but the patient did respond to

combined pyridostigmine and 3,4-diaminopyridine. A patient with a homozygous mutation in agrin, p.G1709R had evidence for disturbed neuromuscular junction structure although it did not directly affect AChR clustering in vitro. Agrin forms part of the core pathway, revolving around the synaptic organizer protein, MuSK, and from the few cases studied thus far it seems that  $\beta 2$ -adrenergic receptor agonists such as salbutamol or ephedrine will also be beneficial for these patients. In a severely affected patient with mutations in SCN4A, endplate potentials of normal amplitude failed to activate the postsynaptic voltage-gated sodium channels. This is due to the rapid inactivation of the  $\text{Na}_v1.4$  channels resulting from the aberrant V1442E. This mutation may show dominant inheritance; however, the other allele also harbored a clinically silent mutation S246L that causes small but detectable biophysical changes (26). In addition to mutations primarily affecting ion channels, it is possible that mutations in structural proteins disrupt neuromuscular transmission. An example is plectin, a structural protein of muscle and skin sometimes mutated in epidermolysis bullosa simplex. In one reported case, plectin expression was absent in muscle and severely reduced in skin. Striated muscle showed ultrastructural abnormalities with abnormal endplates and degeneration of the junctional folds (57), resulting in characteristic myasthenic weakness. Another case of heteroallelic mutations in  $\beta 2$  laminin, *LAMB2*, in a patient who had a kidney transplant has also been reported (58).

## 131.5.8 Synaptic Defects

### 131.5.8.1 Endplate Acetylcholinesterase Deficiency

**131.5.8.1.1 Clinical Features.** This recessive disorder usually presents with generalized weakness at birth or in infancy. Such symptoms together with delayed pupillary light reflexes may help to distinguish these cases from those with the slow-channel syndrome whom they often come to resemble in later life, both at EMG and in the muscle groups affected. Their disabilities probably again reflect the effects of prolonged ACh action, with AChR desensitization, persistent depolarization, and eventual endplate myopathy. Staining of endplates shows a loss or marked reduction in AChE that evidently prolongs the decay phase of the mepps. Morphological changes include small nerve terminals enveloped by Schwann cells, and degeneration of junctional folds. As expected, inhibitors of AChE have no effect or are detrimental, but both ephedrine and salbutamol may be beneficial (59), although the effects tend not to be quite as dramatic as seen in patients with Dok-7 CMS.

**131.5.8.1.2 Molecular Basis.** The AChE consists of enzymatic globular heads (arranged as tetramers or hexamers) that are encoded by the AChE gene on chromosome 7 (60). They are anchored to the basal lamina by the ColQ polypeptide (chromosome 3p24.2). It has a proline-rich attachment domain (PRAD), a central

collagen-like segment and a C-terminal region linking it to the basal lamina. Mutations, which may be homozygous or heteroallelic, have now been identified in each of the ColQ domains (59,61–63), but not yet in the catalytic globular heads. Thus, this disorder results from the failure to localize AChE at the endplate.

## 131.5.9 Presynaptic Defects

There are several reports of presynaptic defects in ACh release. They include inherited disorders resembling the LEMS (64) and also “familial infantile myasthenia,” which has recently been renamed as CMS with episodic apnea (73rd ENMC International Workshop: Congenital Myasthenic Syndromes), although this terminology is not ideal because many cases with RAPSN mutations show similar apneic episodes. The children with presynaptic defects may appear largely normal until a crisis develops, for example, during a bout of fever or stress. As in other presynaptic defects, the extraocular muscles are largely spared. Again the episodic crises, which may be life-threatening, become less frequent with age. On EMG, abnormal decrement is not found in resting muscle but is apparent after stimulation at 10 Hz for several minutes. Confirmation of diagnosis requires a normal-amplitude mepp in the resting state, abnormal decrease in mepp amplitude after 10-Hz stimulation for 5 min, and a normal number of AChR per endplate. These conditions usually respond to anticholinesterase medication.

**131.5.9.1 Molecular Basis.** Mutations in the gene encoding choline acetyltransferase (ChAT) have been shown to underlie some CMSs with episodic apnea (65). The mutations may markedly reduce ChAT expression or significantly impair its catalytic activity. It is not yet clear why there is selective vulnerability of the neuromuscular synapse to defective ACh resynthesis.

## 131.5.10 Fetal Akinesia Deformation Sequence (FADS)—Neuromuscular Junction Proteins

Neuromuscular transmission at nearly all normal adult muscle endplates is mediated by AChR consisting of  $\alpha 2\beta\delta\epsilon$  subunits, but for crucial periods of fetal development in utero transmission is mediated through the fetal form ( $\alpha 2\beta\delta\gamma$ ) of the AChR. Loss of fetal movement during these periods can lead to a series of developmental abnormalities.

**131.5.10.1 Clinical Features.** Multiple pterygia syndromes or Escobar syndrome is an autosomal recessive condition that manifests in orthopedic and cranial abnormalities. Characteristically, there is short stature, arthrogryposis multiplex congenita, pterygia of the neck and anomalies of the head including low-set ears, ptosis, a pointed and receding chin and high arched palate (66). Intrauterine death and stillbirths are common.

**131.5.10.2 Molecular Basis.** Mutations of the AChR  $\gamma$ -subunit gene *CHRNA7* have been found to underlie many cases of Escobar syndrome (Morgan; Hoffman). The loss of fetal AChR function associated with *CHRNA7* mutations are thought to result in fetal akinesia, which in turn causes the associated multiple developmental abnormalities. Surprisingly, some patients that harbor  $\gamma$ -subunit null alleles can survive, suggesting early expression of the  $\epsilon$ -subunit that partially compensates for loss of the  $\gamma$ -subunit might occur. Following birth, neuromuscular transmission is mediated by adult AChR and patients show little or no progression of their condition. Since the disorder results from lack of neuromuscular transmission at crucial developmental phases, it might be expected that recessive inheritance of loss of function mutations in other essential components of the neuromuscular junction, such as rapsyn, MuSK or DOK7 would also result in fetal akinesia, and indeed cases have been reported with mutations in RAPSN (67), DOK7 (68), and CHRNB1 and CHRNB2 (69).

The congenital myasthenic syndromes can be viewed as a spectrum of disorders, varying from lethal forms that cause death in utero through to those with only mild weakness. Definitive diagnosis of CMS often requires screening of candidate gene loci, followed by functional studies of the identified mutations in cellular systems. As reviewed by Engel and coworkers (1), experienced clinicians can often make a provisional diagnosis from the clinical and EMG features; also, it may be important to test affected muscles. Distinctive clinical features such as mild arthrogryposis at birth, the pattern of muscles affected, and response to anticholinesterase medication may suggest which gene is defective. In biopsied muscle, elongated, patchy or decreased AChE staining or reduced  $^{125}\text{I}$   $\alpha$ -neurotoxin binding may give further valuable diagnostic clues. Parental consanguinity or a positive family history (e.g. with affected siblings) are strongly suggestive of hereditary rather than autoimmune myasthenia, but of course are not essential criteria. Serum anti-AChR antibodies should be sought, although their absence does not exclude autoimmune MG because about 10–15% of cases are “seronegative” in the standard assay (see later). In neonates, it is particularly important to check both for these antibodies and for MG in the mother, partly for the sake of subsequent offspring as well as the proband. Finally, other causes of neonatal weakness, whether genetic (e.g. myotonic dystrophy) or acquired (e.g. botulism), should also be excluded.

## 131.6 ACQUIRED AUTOIMMUNE MYASTHENIA GRAVIS

### 131.6.1 Neonatal Myasthenia Gravis

The babies of about 10% of mothers with autoimmune MG have a transient and usually benign weakness, typically showing general hypotonia with difficulty in

feeding, swallowing, and crying but without prominent ocular signs (70–72). There is surprisingly little evidence of prenatal involvement, and weakness is usually noted within 1–3 days after birth. In more severe cases, there may be respiratory problems requiring assisted ventilation and even exchange transfusion. In most, however, treatment with anticholinesterases in advance of feeding suffices, and can be tapered to zero within the subsequent few weeks (13). It is probably wise to avoid breastfeeding. Only rarely does weakness persist for more than 6 weeks. With improved diagnosis and management, neonatal MG may now be less common than it was in the past.

Usually the maternal MG is the vital diagnostic clue, but the severity of the neonatal myasthenia often correlates poorly with it. Neonatal myasthenia is predicted better by high anti-AChR antibody titers in the mother, particularly against fetal AChR, and especially by the severity of her previous babies' myasthenia (70), which tends to be consistent from sibling to sibling. Conversely, in rare cases, the mother's MG may be diagnosed only because of the transmission to her baby; if so, anti-AChR assays on mother and baby are often invaluable. Occasionally, however, seronegative MG may be transmitted to a baby, supporting its autoimmune etiology. In other rare cases, recurrent severe fetal arthrogryposis occurs (73), sometimes even though the mother is asymptomatic. This suggests an idiosyncratic preference of the mother's antibodies for fetal AChR (74). This syndrome may result in abortion or stillbirth, but less severely affected babies may overcome their handicaps as their AChR matures to the adult form and their maternal antibody levels wane, leaving only mild residual disability.

### 131.6.2 Acquired Myasthenia Gravis

**131.6.2.1 Prevalence.** The overall prevalence of MG is approximately 1 per 5000 in Europe and North America, and does not differ greatly in other countries as far as is known (75). In the Far East, up to 30% of all cases show onset before 10 years of age, or even in infancy, and there are relatively fewer late-onset cases (after age 50 years). By contrast, in the children, the MG is mainly ocular and frequently associates with ophthalmic Graves' disease; whereas anti-AChR antibody titers are often low or negative in the standard assay, use of AChR from extraocular muscle increases the frequency of positivity substantially (76).

**131.6.2.2 Clinical Features.** As reviewed in Engel (77), acquired MG is characterized by weakness of skeletal muscle, which is typically fatigable and thus usually at its worst in the evenings. In all subgroups of patients (Table 131-2) the onset is often insidious but may coincide with infections or periods of stress. It commonly first affects movements of the eyes and, at a later stage, may involve bulbar, neck, hand, limb, or respiratory muscles. Tendon reflexes are usually brisk. In severe

**TABLE 131-2 Subgroups of Myasthenia Gravis Patients in the United Kingdom**

	Seropositive Generalized Myasthenia Gravis				Seronegative Generalized	
	Early-Onset	Late-Onset	Thymoma	Ocular MG	Anti-MuSK Pos	Neg
Prevalence	40%	40%	10–15%	10–20%	5–10%	~10% (% of total cases)
Onset age	<40 years	>40 years	15–90 years	0–90 years	10–50 years	10–50 years
Male: female	1:4	1.5:1	1.3:1	1.7:1	1:2	1:3
Serum anti-AChR: prevalence/titer	100% High	100% Low–medium	100% Medium	~60% Low	0% –	0% –
Thymic changes hyperplasia	Follicular hyperplasia	Atrophy hyperplasia	Thymoma	None or mild	Normal-for-age	Normal or mild
Striated muscle antibody	Rare	30–40%	100%	Rare	Rare	Rare
HLA association	(A1,B8,DR3)	(A3,B7,DR2) (n = 90)	Not detected (n = 60)	Not detected (n = 10)	Not detected (n = 10)	Not detected

cases, difficulties in swallowing and breathing can be life-threatening. Its mortality has declined greatly since the advent of assisted ventilation, plasma exchange, and particularly, corticosteroids. There are excellent handbooks on its natural history and therapy (77,78).

**131.6.2.3 Patient Subgroups and Diagnosis.** The classification and diagnosis of patients (see Table 131-2) have also been greatly helped by the highly specific assay for autoantibodies to the AChR (10,79). In whites, MG only occasionally begins before puberty. When it does, there may rarely be recurring apneic attacks/respiratory crises, and the parents should be trained in their management. Otherwise, the myasthenia in this juvenile MG subgroup resembles that in other early-onset cases, including the response to thymectomy (see later, and References (80) and (81)). Typical early-onset MG in the United Kingdom appears in the teens and 20s, and has a heavy female bias (see Table 131-2). The characteristic thymic abnormalities and human leukocyte antigen (HLA) associations distinguish these patients sharply from those of patients with the late-onset condition (see later). The clinical course in early-onset cases is very variable; 20–30% of patients experience long-term remissions, especially after thymectomy. The myasthenia may fluctuate, and in another 20–30%, the disease may progress and require long-term immunosuppressive therapy. Patients with late-onset disease often show more stable behavior, but MG associated with thymoma tends to deteriorate, especially after thymectomy. Patients with pure extraocular muscle involvement for at least 3 years rarely progress to generalized MG, and their serum antibody levels tend to be low or undetectable (10). In these cases, and in “seronegative” patients with typical generalized MG symptoms, there is good evidence for other pathogenic autoantibodies that are not measured in the standard assay (7). These recognize MuSK in some cases, especially those from southeastern Europe; their MG is often more difficult to control (82).

The diagnosis depends principally on the clinical picture, on the detection of anti-AChR antibodies by radioimmunoassay (10), and on EMG, which shows typical

decrement and jitter (5). A relatively sensitive and specific bedside test that distinguishes myasthenia from other causes of ptosis involves application of crushed ice in a latex glove to the eye. This leads to improvement of ptosis in MG and has been reported to have a sensitivity of 89% (83). In the edrophonium (Tensilon) test, strength is measured (e.g. by peak expiratory flow or degree of ptosis) before and after intravenous injection of short-acting anticholinesterase drugs. Because it carries some risk, this test is now mainly reserved for seronegative patients, in whom the diagnosis is reinforced by EMG, although neither test is totally specific for MG; similar abnormalities can occur both in congenital myasthenias and in the LEMS. MuSK antibodies are more prevalent in on the latitude of Mediterranean countries and are rarer further from the equator. MuSK positive patients are more likely to have early bulbar and respiratory symptoms with less severe limb involvement and only rare ocular symptoms (72). The clinical neurophysiology in MuSK usually shows abnormal SFEMG of facial muscles but RNS of limb muscles can be normal.

A small proportion of patients remain consistently negative for both AChR and MuSK antibodies. Clinical features and thymic pathology imply that seronegative myasthenia gravis (SNMG) is similar to MG caused by AChR antibodies. This has led to the hypothesis that the patients have antibodies to AChR that are not detected with conventional assays. Indeed a proportion of such patients can be shown to have antibodies that bind AChRs expressed in a cell lines in which AChR are aggregated on the cell surface by co-expression with the AChR-clustering protein, rapsyn (53). There are also reports of serum antibodies to the MuSK associated protein LRP4 (84), although this is rare and it is unclear whether not this antibodies are pathogenic.

**131.6.2.4 Pathology.** Pathological changes in striated muscle are not dramatic. Especially in thymoma cases, there may be sporadic foci of lymphocytes (lymphorrhages) not normally related to the endplates, which themselves are only mildly or minimally infiltrated by macrophages and occasional lymphocytes.

Immunolabeling has shown immunoglobulin G (IgG) and complement deposits on the postsynaptic membrane (85), and these include the membrane attack complex (i.e. even C9). The resulting damage greatly reduces the complexity of the synaptic folds, and thus the area of AChR-bearing membrane. Accelerated degradation of AChRs (by cross-linking and shedding) exaggerates this reduction in AChR numbers (86), which largely accounts for the myasthenic weakness. Direct blockade of AChR function is probably important only in a minority of cases (87).

### 131.6.3 Thymomas

Thymomas occur in 10–20% of myasthenics worldwide; although little is known of their etiology, mutations in the neoplastic epithelial cells vary strikingly between thymomas. In contrast with the other subgroups, these patients almost always have antibodies to striated muscle antigens as well as AChR (88). The neoplastic cells in the thymoma are usually mainly of cortical epithelial origin (89); this is the uniquely thymic cell type that normally “positively selects” developing T cells that can recognize foreign peptides when bound to self-HLA class I or class II molecules. The tumors usually resemble disorganized thymic cortex, both histologically and functionally, and frequently generate very many thymocytes and maturing T lymphocytes (89). Some of these might be aberrantly selected by AChR or striational epitopes expressed by the epithelial cells (88), and could subsequently initiate antibody responses to them after emigrating to the periphery (reviewed in Reference (90)). In theory, these tumors could instead be exporting T cells that have not been properly rendered self-tolerant in these disorganized tumors. Because MG develops in so many (30–50%), of all thymoma patients, and other autoimmune associations are rare (91), active selection seems more likely.

**131.6.3.1 Follicular Hyperplasia.** In the follicular hyperplasia seen in most early-onset cases, the changes are completely different, and are mainly medullary. The residual thymic epithelium is compressed by perivascular infiltrates of lymph node-type T-cell zones and germinal centers (reviewed in Reference (92)). Although these include mature/recirculating T and B lymphocytes specific for extrinsic antigens (e.g. influenza virus) (93), AChR-specific plasma cells are selectively activated in situ, and spontaneously secrete antibodies in culture. Indeed, these appear to be end-products of ongoing mutations in the germinal centers, which often include AChR-specific cells. They may be activated by the rare muscle-like myoid cells (94), found in both the normal and MG thymic medulla that express AChR of the fetal type. This might also explain the frequent improvement in these patients’ myasthenia after thymectomy, but it is still controversial (90). Similar changes are seen in some patients with neither anti-AChR nor anti-MuSK

antibodies, but they are uncommon in those with anti-MuSK.

## 131.7 IMMUNOGENETIC ASSOCIATIONS

In a summary of monozygotic twins with MG, only six of 18 pairs were concordant for symptoms and seven for anti-AChR antibody (95), and this figure is probably inflated by the usual biased reporting of concordant pairs. Nevertheless, all of 13 dizygotic pairs were discordant, implying a substantial genetic component to their susceptibility. Recurrence of MG in close relatives occurs in only about 2% of patients, who occasionally even have a thymoma (66,93,96). There is no obviously preferred transmission pattern (e.g. mother-to-daughter), and multiplex families are rare (97). There are also elevated frequencies of other autoimmune diseases and autoantibodies in MG (96,98), and in first-degree relatives of patients, especially on the mother’s side of the family but there have been no systematic immunogenetic studies such as those reported for thyroid disease (99).

A predisposition to the disorder is observed for certain alleles of some AChR subunit genes, especially the  $\alpha$ -subunit (100–102) and possibly the  $\delta$ -subunit (103,104). These associations are seen in both early- and late-onset MG. Because the  $\alpha$ -subunit association is almost confined to subjects with HLA-DQ5 (105), it suggests influences of AChR expression on induction of autoimmune T cell responses, or possibly on the course of the MG.

### 131.7.1 Early-Onset Myasthenia Gravis

In whites with early-onset MG, the strong association with HLA DR3, B8, and A1 (96), and its restriction to this subgroup were soon noted (98). Initially, the particularly strong linkage disequilibrium in this haplotype helped to highlight the association but has since made precise localization of the key susceptibility genes more difficult than in some other autoimmune diseases. MG is an antibody-mediated disease, and helper T cells, which recognize peptides presented by HLA-class II antigens, are widely held responsible for initiating the autoimmune response. Nevertheless, in northern Europeans, the associations have consistently been slightly stronger with HLA-B8 in the class I region than DR3 in class II (78,96,98). There may be predisposing loci in both class I and class II regions, or near the TNF/Lymphotoxin locus in class III, especially when anti-AChR antibody titers are high (101,106). There are likely to be further contributions from other immunological genes, for example, encoding cytokines or adhesion molecules (107). The female bias, the stronger HLA-DR3 and B8 associations in females, and their restriction to the child-bearing years, are all highly suggestive of hormonal interactions (108). Other autoimmune disorders are common in early-onset MG, especially on the mother’s side of the family.

### 131.7.2 Myasthenia Gravis in Chinese and Japanese

By contrast, in Chinese and Japanese MG patients, the most consistent associations are with the HLA-DR9-B46 haplotype (56,109), as in autoimmune thyroid disease. Interestingly, the association in MG is even stronger with DR9 than with B46, and it is most pronounced in the patients with earliest onset (109) in apparent contrast with the rare juvenile MG in northern Europeans. Again, familial recurrence is rare (109), and some distinctive provoking factor in the Far East seems likely.

### 131.7.3 Other Subgroups

In northern European men with late-onset MG, modest increases in HLA-DR7 (103) and in HLA-DR2 and -B7 replace those in DR3 and B8, although the associations and linkage disequilibrium are weaker (110). Finally, it is an intriguing puzzle that patients with thymoma or with pure ocular MG have shown no consistent HLA associations, even though the disorder is again clearly autoimmune. Perhaps the thymoma provides such a strong stimulus that it overrides genetic limitations.

### 131.7.4 Immunoglobulin Genes

In Japanese patients, there are also relatively strong associations with immunoglobulin heavy chain (IgH) constant region allotypes (111). They were noted in most subgroups of Japanese patients, especially in those of early onset or with thymoma, but have not been seen in the corresponding white or Chinese subgroups. There could be heritable differences in the variable region genes, perhaps encoding particularly pathogenic anti-AChR antibody specificities.

### 131.7.5 Conclusion

In conclusion, the striking differences, both in immunogenetics and in thymic histology, strongly suggest that there are different provoking factors in these subgroups (98). One particularly telling example is the typical seropositive generalized MG seen in about 1% of patients taking the drug d(-) penicillamine for rheumatoid arthritis or Wilson's disease. The antibodies and weakness disappear after withdrawal of this drug. These patients often have HLA-DR1 or DR7 with or without HLA-B8 (105), whereas other autoimmune complications of this therapy show different associations. Perhaps this very simple drug, with its reactive sulfhydryl group, modifies resident peptides in HLA-DR1 or linked molecules so as to provoke an AChR-specific T cell response.

## 131.8 MANAGEMENT

First-line therapy in MG is with anticholinesterases, especially the long-acting pyridostigmine, and in many

patients, this agent alone affords adequate control, although ocular weakness may respond poorly. In young patients with seropositive generalized MG, most neurologists favor early thymectomy, because about two thirds of patients can subsequently be maintained on pyridostigmine alone. The benefits of thymectomy have never been rigorously proved (e.g. in a randomized trial) and about 30% of patients require additional immunosuppressive therapy, for example, with alternate day corticosteroids, perhaps supplemented with azathioprine (to reduce the steroid dose). Although the thymomas are usually slow growing, their local spread can be dangerous and they should be sought and removed except in elderly patients and very frail cases. Invasive thymomas may recur without any change in either the anti-AChR antibodies or in the symptoms of the patients, who should therefore be regularly monitored radiographically. Perhaps surprisingly, the MG in these patients seldom resolves after surgery. Plasma exchange and intravenous immunoglobulin are usually reserved for crises and to improve strength preoperatively. Management strategies for MG are much more extensively reviewed in the handbooks cited earlier and by Newsom-Davis (112).

## 131.9 LAMBERT-EATON MYASTHENIC SYNDROME

LEMS is a rare disorder, characterized by proximal muscle weakness, diminished tendon reflexes, and autonomic symptoms, especially dry mouth, constipation, and impotence. The cardinal physiological defect is in ACh release at nerve endings, apparently caused by autoantibodies to voltage-gated  $\text{Ca}^{2+}$  channels (VGCC) (113). In particular, there is a reduced number of packages of ACh released after each nerve impulse (quantal content), and transmission is improved after maximal voluntary contraction of the relevant muscle (post-tetanic potentiation). The autonomic symptoms and EMG signs are helpful features in distinguishing LEMS from MG.

### 131.9.1 Etiopathogenesis

LEMS is a classic paraneoplastic syndrome (114). About 60% of cases have a small cell lung cancer (SCLC), and about 3% of patients with SCLC develop LEMS (although they may not always be recognized). These tumors are strongly associated with tobacco smoking, but little is known of their genetics. The onset of LEMS often precedes the diagnosis of the tumor by up to 5 years and can thus be a vital early warning. This condition tends to ameliorate if the tumors can be removed or destroyed (115), suggesting that they are driving the autoantibody response (116). In support of that, cultured SCLC cells express VGCC that are recognized by the patients' autoantibodies (117).

Equally in patients without SCLC, in whom there are no known provoking factors, LEMS symptoms improve

2–4 weeks after plasma exchange, and its physiological defects can also be passively transferred to mice with patients' Ig (118). Nerve terminals show disorganization of the active zone particles that are associated with the target  $\text{Ca}^{2+}$  channels, a disruption very similar to that seen in the patients (119). This effect probably depends mainly on cross-linking by divalent antibodies rather than on complement-mediated damage. Apart from striking type I fiber loss in some cases (120), there is no gross muscle pathology. Recent work on the different subunits and subtypes of VGCC shows that the  $\alpha 1A$  subunit of the P/Q channel type is the target in LEMS (121,122). The autoantibodies can be assayed using detergent-solubilized  $\text{Ca}^{2+}$  channels from human cerebellum prelabeled with appropriate toxins, especially from the marine snail *Conus magus*, assays that are now highly efficient and specific (12). As in MG, titers tend to decline after plasma exchange or immunosuppressive therapy (123).

### 131.9.2 Genetics

Because the autoimmune response must often begin when the tumors are small, these patients are presumably high responders. In a small study, they have shown modest IgH associations (with the Gml, 2, 21 haplotype) (124) that require confirmation. In the patients without SCLC, the onset age ranges from 10 to 70 years, and there is no strong sex bias or familial incidence. There is a considerably increased risk of other autoimmune diseases (especially vitiligo, alopecia, and thyroid disease) (124). There is also a significant increase in HLA-DR3 and B8 frequencies (125,126).

### 131.9.3 Management

In all cases an intensive search for lung tumors should be initiated at diagnosis and regularly thereafter. Patients with a history of smoking, cerebellar dysfunction and older patients with rapid progression of symptoms are more likely to have an underlying malignancy (117). In patients with SCLC, therapy for the tumor must obviously take priority, and often, by itself, resolves LEMS (115). Interestingly, the tumors apparently have a better prognosis in patients who also have LEMS (127). In any patients, the drug 3,4-diaminopyridine often enhances neuromuscular transmission (Versheuren et al.). Immunosuppression with corticosteroids with or without azathioprine is reliably effective, as is plasma exchange in crises. Therapy in LEMS has been reviewed (113).

## Motor Neuron Disease

Teepu Siddique, H X Deng and Senda Ajroud-Driss

Department of Neurology and Clinical Neurosciences and Department of Cell and Molecular Biology, Northwestern University Feinberg School of Medicine, Chicago, IL, USA

This article is a revision of the previous edition article by Teepu Siddique and George H Gorrie, volume 3, pp 3088–3098.

### 132.1 INTRODUCTION

Amyotrophic lateral sclerosis (ALS), also known as Lou Gehrig disease, motor neuron disease or Charcot disease, is an adult onset, progressive, neurodegenerative disorder involving the large motor neurons of the brain and the spinal cord. It produces a characteristic clinical picture with weakness and wasting of the limbs and bulbar muscles, leading to death from respiratory failure within five years. It was in 1874 that the French neurologist Jean Martin Charcot defined the clinical and pathological feature of the disease and gave it its name of amyotrophic lateral sclerosis. Sir William Osler recognized the hereditary component of the condition in 1880. More than a century later, the first gene linked to adult onset autosomal dominant ALS, Cu, Zn superoxide dismutase (*SOD1*) was identified and that led to the engineering of the first transgenic animal model of the disease. This mouse model became the backbone of ALS research and has been used worldwide to investigate pathogenic mechanisms and to test experimental therapies. In the past decade the list of genes causing motor neuron disease grew significantly, with the identification of *ALSIN*, which causes a rare form of recessive juvenile onset ALS with predominant upper motor neuron features, or *ALS2*, followed by the discovery of *SENATAXIN* (*SETX*) mutations causing *ALS4* and *VAPB* causing *ALS8*. The identification of TDP43 as the major disease protein in the ubiquitinated inclusions in ALS and frontotemporal dementia led to the detection of mutations in *TDP43* in a subset of patients with familial ALS or *ALS10*. The function of TDP43 as a DNA/RNA binding protein shifted ALS research to the role of DNA/RNA metabolism in motor neuron degeneration. Mutations in *FUS/TLS*, a gene that encodes a protein of similar function to TDP43, were found to cause *ALS6* and further implicated DNA/RNA fate in the pathogenesis of ALS. Mutations of the Optineurin (*OPTN*) and Valosin-Containing Protein (*VCP*) genes were recently linked to autosomal dominant ALS, whereas SGP11-associated gene *SPATACSIN* was found to cause autosomal recessive juvenile ALS or *ALS5*.

Recent breakthroughs in ALS genetics are the discoveries of ubiquilin2 (*UBQLN2*) as the causative gene of X-linked juvenile and adult-onset ALS and ALS with dementia, and the hexanucleotide repeat expansion in *C9ORF72* as the cause of ALS/Dementia and ALS linked to chromosome 9p21. Several other genes such as Angiogenin (*ANG*), *FIG4* and D amino acid oxidase (*DAO*) make small contributions to familial ALS, expanding the pathogenic mechanisms which lead to motor neuron death.

Although genetic studies of familial ALS have helped to better understand some of the molecular pathways involved in motor neuron degeneration, 84% of ALS is sporadic, without clearly defined etiology. The completion of the human genome project and the international Hap Map project together with the development of high throughput Genome-Wide Association Studies (GWAS), whole exome and whole genome sequencing technology have opened the door to the identification of genetic risk factors for sporadic ALS or provided important clues to disease pathogenesis. The interpretation of GWAS results and the translation of the genetic findings had proved to be challenging, since results were not replicated in different populations. Of all the susceptibility genes revealed by the different GWAS studies, the paraoxonase gene cluster has been extensively examined in the past years and has emerged as a robust genetic risk factor, although the result of the GWAS examination of its association with sporadic ALS is controversial. Interestingly, the ALS-FTD locus on 9p21 is also associated with sporadic ALS with a very high statistical probability, but the cohort of patients used initially may have been contaminated with familial cases. Recent studies show that about 5% of apparently sporadic cases have an expanded hexanucleotide repeat in their *C9ORF72* gene.

### 132.2 HISTORY

The term “Amyotrophic Lateral Sclerosis” was coined by Jean Martin Charcot in his 1874 clinico-pathological description of the disease; however Charcot was not

the first to describe ALS. In 1850, Aran published data from a series of eleven patients with progressive muscle weakness and atrophy of the limbs that he called progressive muscular atrophy (PMA). Duchenne was given some credit in the description of this disease, which was often referred to as Aran–Duchenne disease. Both Aran and Duchenne considered PMA a muscle disease, until Cruveilhier in 1853 studied the autopsy of one of Aran's patients, noted atrophy of the anterior spinal roots and the motor nerves and suspected a neurogenic etiology for the syndrome. Duchenne was the first to describe progressive bulbar palsy that he called “glosso–labial–laryngeal paralysis” and Erb was the first to describe primary lateral sclerosis (PLS) in 1875. Gowers was the first to group the three phenotypes under the same syndrome that was later named motor neuron disease by W. Russell Brain.

Although Aran may have alluded to the familial nature of ALS, it was Sir William Osler in 1880 that recognized that the Farr family of Vermont had a dominantly inherited form of ALS. It was not until a century later that genetic analyses of ALS kindreds, including the Farr family, led to the identification of *SOD1* as the first causative gene for ALS (1–4). Although genetic discoveries were initially slow, they quickly picked up in this past decade with the discovery of more than ten genes linked to familial motor neuron disease and the generation of a plethora of animal models from fruit flies and zebra fish to mice and rats. More recently, the tools of modern genetics, such as genome wide association studies (GWAS), have been applied to sporadic ALS in the quest for susceptibility genes that may help us better understand the complex genetic and environmental interactions that lead to this disease.

Because the etiology of this disease is mostly unknown, it is difficult to develop adequate therapies and despite all the genetic progress, clinical trials remain deceiving. Riluzole is the only FDA approved treatment, and has only a marginal effect on disease progression. The recent generation of patient specific motor neurons from induced pluripotent stem cells (iPS) obtained through the epigenetic reprogramming of skin fibroblasts (5) will open new horizons for in vivo disease modeling and drug discovery.

### 132.3 EPIDEMIOLOGY

ALS is the most common adult onset motor neuron disease; it has an incidence of about 2/100,000 and a prevalence of approximately 6/100,000 (6). The incidence of ALS is higher in men with a male to female ratio of 1.5:16, the incidence also increases with age, mainly between the ages of 55 and 65.

The frequency of ALS seems to be uniform around the world except for the western Pacific form of ALS. In 1950s, ALS in association with dementia and Parkinsonism was reported to occur 50–100 times more frequently in the Chamorro people of Guam, in the Kii peninsula of Japan and in the western part of New Guinea (7,8).

Although the incidence of this disease has significantly decreased in the past decades, its etiology remains elusive.

About 10% of ALS patients have either a first, second or third degree affected relative. Familial ALS can be transmitted as an autosomal dominant or recessive trait. Adult onset autosomal dominant transmission is more common than recessive transmission. Recessive transmission is usually limited to patients with juvenile onset ALS. Our group has reported five families with an unusual transmission of ALS as a dominant X-linked trait (9).

### 132.4 CLINICAL FEATURES

ALS presents in about two third of the patients with an asymmetric weakness and atrophy of one of the limbs (spinal onset ALS). Foot drop, difficulty in walking, loss of fine hand movements or shoulder weakness is often reported by patients as an early symptom, sometimes preceded by cramps. In the remaining one-third of the patients, weakness starts in the bulbar muscles (bulbar onset ALS), causing dysarthria followed by dysphagia. Physical examination reveals a combination of upper and lower motor neuron signs in the motor segment with features of weakness, atrophy and fasciculations in the affected muscle groups, together with brisk tendon reflexes and the absence of, or minimal sensory findings. The disease is progressive and usually spreads to anatomically connected segments of the neuroaxis, and most patients go on to develop bulbar and eventually respiratory symptoms that lead to death from respiratory muscle weakness. In a rare subset of patients, respiratory muscle weakness can be the presenting symptom. The extraocular muscles are usually not affected, while bladder and bowel sphincters are spared until late in the disease. Patient with ALS have normal cognition but neuropsychological testing may reveal frontal network dysfunction and personality traits coincident with perfectionism and elements of inflexibility with poor insight and judgment in about half the patients. Dementia of the frontal-temporal variant has been recognized to occur in association with ALS in a minority of cases.

The El Escorial criteria have been developed to standardize the diagnosis for clinical research (10). The diagnosis of ALS is based on history and an examination that shows progressive upper and lower motor neuron findings. The diagnosis is supported by results from electrophysiological study of peripheral nerve and muscle, MRI imaging of the central nervous system and laboratory tests that help exclude disorders mimicking ALS, such as multifocal motor neuropathy with conduction blocks, spinal spondylosis, syringobulbia, etc.

While ALS is incurable, symptomatic management provided in multidisciplinary ALS clinics improves patient quality of life and has a positive influence on disease progression. Unfortunately, the progression of the disease is relentless and most patients die within five years of disease onset.

### 132.5 CLINICAL VARIANTS OF AMYOTROPHIC LATERAL SCLEROSIS

Progressive muscular atrophy, a pure lower motor neuron syndrome, primary lateral sclerosis, a pure upper motor neuron syndrome, progressive bulbar palsy, brachial amyotrophic diplegia and monomelic atrophy are variants of ALS that have different clinical presentations, rate of progression and prognosis. It is not clear whether they represent entirely separate disease entities or a continuum of the same disorder. Family studies favor the latter.

### 132.6 PATHOLOGY

The pathology of ALS is characterized by the loss of pyramidal Betz cells in the motor cortex, as well as loss and degeneration of the large anterior horn cells of the spinal cord and lower cranial motor nuclei of the brainstem (11). The degenerating motor neurons display intracellular aggregates forming distinct inclusion bodies: ubiquitinated inclusions, Bunina bodies and hyaline conglomerate inclusions. Ubiquitinated inclusions are mainly found in the lower motor neurons of the brainstem and spinal cord. They can have a filamentous, skein-like or a rounded compact shape and are called Lewy body-like inclusions. TDP43 was recently found to be a major constituent of the ubiquitinated inclusions in sporadic ALS (12). Bunina bodies are small eosinophilic, hyaline intracytoplasmic inclusions that stain positive for cystatin C and transferrin and are considered specific to ALS (13). Hyaline conglomerates are highly immunoreactive for neurofilaments and are mainly found in the motor neurons of familial ALS patients.

Aside from the obvious selective neuronal loss and the morphological changes in the remaining motor neurons affected, ALS tissue also shows alteration of non-neuronal structures. Affected areas have been shown to be the site of a robust glial reaction composed of abundant activated microglia and astrocytes (14).

### 132.7 GENETICS OF FAMILIAL AMYOTROPHIC LATERAL SCLEROSIS

#### 132.7.1 ALS1 or SOD1-Linked ALS

One of the important breakthroughs in ALS research was the discovery in 1993 that mutations in the gene encoding the enzyme copper-zinc superoxide dismutase (*SOD1*) were associated with familial ALS (1,2). Since that report, more than 150 mutations in *SOD1* have been described, consisting mainly of amino acid substitutions, and more rarely of amino acid deletions or truncations. *SOD1* mutations account for 20% of familial ALS and for 2–7% of sporadic patients ([www.alsod.org](http://www.alsod.org)). The mode of inheritance is autosomal dominant with age dependent penetrance, except for the D90A mutation, which is transmitted in an autosomal dominant or recessive

fashion. In the US, the A4V mutation is the most common mutation, followed by the I113T mutations (15). In the UK, it is the I113T mutation (16), in Germany the R115G mutation (17) and the D90A is the most common mutation in patients of Scandinavian origin (18).

The clinical phenotype of patients with familial ALS due to *SOD1* mutations tend to show a preponderance of lower motor neuron features and more frequently presents with signs in the lower limb, with loss of the Achilles reflex (T. Siddique unpublished observation). This type of monomelic presentation can persist for many months before progressing and is reflected in the revised El-Escorial criteria (19).

The mean age of *SOD1* linked FALS is  $45.5 \pm 8.9$  (3) which is lower than that of sporadic ALS and the mean disease duration is of  $3.4 \pm 4.5$  years (3). There is a significant variability in age of onset and disease progression based on the type of the mutation and sometimes even in families with the same mutation. The A4V mutation has an aggressive, rapid course with a mean survival time of  $1.0 \pm 0.4$  years (3,4). In comparison, the G37R, G41D, H46R and G93C mutations have been associated with a more prolonged survival time of at least 10 years (3,15). The I113T, G93R and G85R mutations have been reported to cause a marked variability in disease progression from about two years to one or two decades (20). The I113T mutation has a reduced penetrance, (20) is one of the most common worldwide mutations, and is most frequently found in apparently sporadic ALS patients.

To explain the high prevalence of the A4V mutation in the United States, Saeed and colleagues determined that the North American A4V mutation arose from two founders, Native American (82%) and European (18%), about 400–500 years ago at the time of Jamestown and Plymouth landing (4).

The homozygous D90A mutation has a characteristic phenotype, with progression of symptoms in two phases: the preparetic phase characterized by low back pain, leg pain, stiffness and cramps in the legs for months or even years, followed by the paretic phase, with insidious onset of weakness in one leg with absent deep tendon reflex distally but brisk proximally. Patients sometime have atypical features such as intermittent ataxia and bladder disturbances. The disease has a slow progression, with mean survival of 13 years (18).

Unlike sporadic ALS, the neuropathology of *SOD1*-linked ALS is characterized by relative sparing of the motor cortex, slight or mild corticospinal tract involvement that contrasts with the severe atrophy of the anterior roots and the degeneration of lower motor neurons. Certain *SOD1* mutations such as the A4V, I113T and E100G mutations are also characterized by the involvement of the dorsal columns and the atrophy of the posterior roots (21,22). The cell bodies of surviving motor neurons contain hyaline conglomerate inclusions that are specific for certain *SOD1* mutations and Lewy body-like

inclusions. These inclusions are immunoreactive for SOD1 but not for TDP 43 or FUS (11,22,23). Bunina bodies are not a feature of SOD1 familial ALS (11).

Superoxide dismutases (SOD) are a group of enzymes that catalyze the dismutation of superoxide radicals ( $O_2^-$ ) to molecular oxygen ( $O_2$ ) and hydrogen peroxide ( $H_2O_2$ ), providing cellular defense against reactive oxygen species (24).

There are three isoforms of SOD in humans: cytosolic copper and zinc superoxide dismutase (SOD1, Cu, Zn SOD) encoded by chromosome 21q22, mitochondrial manganese superoxide dismutase (SOD2, MnSOD) encoded by chromosome 6q25 and extracellular superoxide dismutase (SOD3, EC-SOD) encoded by chromosome 4p15.

SOD2 or SOD3 mutations have not been described in ALS patients.

The *SOD1* gene contains five exons and four introns that are transcribed in five splice variants (25). SOD1 is a ubiquitously expressed and highly conserved 153 amino acid protein. It is composed of two identical subunits that form a 32 kDa homodimer, with their active site facing in opposite directions. Most of the protein is folded into an eight-strand beta-barrel and is stabilized by extensive hydrogen bonding. Each subunit contains a copper and zinc binding site and is held together by a disulfide bridge between cysteines 57 and 146 (26).

The role of *SOD1* mutations in familial ALS continues to be investigated. Most of our current understanding of the pathogenic role of mutant *SOD1* comes from the study of transgenic rodents that over-express mutant *SOD1*, and in particular from the widely used mouse model that over-expresses SOD1<sup>G93A</sup> mutation, originally developed by Gurney et al. in 1994 (27). The fact that mice deficient in *sod1* gene or over-expressing wild type *SOD1* do not develop motor neuron disease suggested early on that mutant *SOD1* acquired new toxic properties. The main toxicity of mutant *SOD1* is apparently independent of its enzymatic function, since the G93A mouse model develops progressive motor neuron degeneration despite high SOD1 activity levels, (27) while other rodents with the G85R mutation also develop an ALS-like phenotype but have reduced enzymatic activity (28). The development and the severity of the ALS-like phenotype in the transgenic animal depend on mRNA levels of mutant proteins, with gene dosage affecting the life span of the animal. Reduction of SOD1 expression using RNA interference in the G93A mouse model resulted in delayed disease onset and prolonged survival of the animal (29).

Mutation in *SOD1* causes conformational change and misfolding of the protein, which induces the formation of the aggregates observed in the spinal cord of familial ALS patients and the transgenic animals (30). Although the exact toxic mechanism by which the misfolded SOD1 causes the death of motor neurons is not fully known, many studies have demonstrated that the misfolded

protein causes mitochondrial dysfunction (31,32), disrupts axonal transport (33), overloads the unfolded protein response and causes ER stress (34).

SOD1 aggregates/inclusions in lower motor neurons are a prominent pathological feature in ALS patients with *SOD1* mutations and transgenic mouse models overexpressing mutant *SOD1*. These SOD1 aggregates appear to be specific to SOD1-linked, but not other types of ALS. Deng et al. proposed an oxidation-mediated protein aggregation hypothesis to explain the molecular mechanism of SOD1 aggregation. They hypothesized that the ALS-linked SOD1 aggregates are formed by SOD1 dimers and multimers, which are crosslinked through intermolecular disulfide bonds via oxidation of cysteine residues in SOD1. Consistent with this hypothesis, they have shown SOD1 dimers and multimers that are cross-linked by disulfide bonds in mutant *SOD1* transgenic mice. Moreover, they observed that wild-type *SOD1* could exacerbate the ALS phenotype or also convert an unaffected phenotype to an ALS phenotype in mutant *SOD1* transgenic mouse models. They demonstrated that the effects of wild-type *SOD1* on mouse phenotype are associated with a recruitment of wild-type SOD1 into aggregates by mutant *SOD1* reminiscent of prion-like behavior. This is consistent with the concept of the spread of the disease foci in the neural space. These data, therefore, have provided the first evidence that links protein oxidation and protein aggregation to neurodegeneration. The molecular mechanisms of protein aggregation in other types of ALS still remain elusive (31).

The role of non-neuronal cells in motor neuron degeneration and disease progression has also been the subject of intense debate. Mutant *SOD1*-specific expression in neurons is sufficient to induce motor neuron degeneration and paralysis in transgenic mice (35). It seems that the toxicity of mutant *SOD1* in motor neurons is necessary for disease initiation, and mutant *SOD1* damage in the glia may play a possible role in disease progression (36) through excretion of SOD1 and its uptake by motor neurons.

### 132.7.2 ALS2 or ALSIN-Linked ALS

In a large inbred Tunisian family with recessive juvenile ALS, Hentati et al. established linkages to chromosome 2q33–35 (37). The disease was characterized by early age of onset (3–23) and predominance of upper motor neuron signs. Homozygous deletions in the *ALSIN* gene were subsequently identified by two independent groups (38,39). *ALSIN* gene mutations were also found to cause juvenile primary lateral sclerosis (39) and infantile ascending hereditary spastic paraparesis (40).

The *ALSIN* gene has 34 exons and produces alsin protein, which is ubiquitously expressed and predicted to have a molecular mass of 184 kDa. It is alternatively spliced in two transcripts: a short 396 amino acid form and long 1657 amino acid form. The protein has multiple domains, including a guanine nucleotide exchange

factor homology domain that was shown to activate a small GTPase belonging to the Ras superfamily, a pleckstrin homology domain and a vacuolar protein sorting nine domain (38,39).

It was suggested early on that alsin may be involved in vesicle transport. Recently alsin was shown to be an important regulator of Rab5-mediated endosomal trafficking and degradation (41). Alsin knockout mice have been generated by independent investigators; they develop rather a mild phenotype characterized by poor performance on motor coordination tests and distal corticospinal tract degeneration without apparent motor neuron pathology, suggesting that ALS2 is predominantly a distal axonopathy (42).

### 132.7.3 ALS4 or SENATAXIN-Linked ALS

ALS4, also known as distal hereditary motor neuropathy with pyramidal features, is a rare, juvenile onset, autosomal dominant form of ALS characterized clinically by slowly progressing limb weakness, severe muscle wasting, pyramidal signs, the absence of overt sensory abnormalities or bulbar involvement and a normal life span (43).

Linkage was initially established to chromosome 9q34 in a large Maryland kindred (43) and heterozygous mutations were found in Senataxin gene (*SETX*) in 2004 in this family and in two additional ones that showed linkage to the same region (44). Homozygous mutations in the Senataxin gene lead to an unrelated disorder: ataxia-oculomotor apraxia 2 (45).

The Senataxin gene contains 26 exons and encodes a 302.8 kDa protein (44). The protein was named senataxin because of its yeast ortholog Sen1p—a splicing endonuclease. It contains a DNA/RNA helicase domain with strong homology to RENT1 and IGHMB2, two members of the superfamily I of helicases. RENT1 has been shown to be involved in non-sense mediated mRNA decay (46) and IGHMB2, a DNA binding protein that causes spinal muscular atrophy with respiratory distress (SMARD) (47).

Senataxin is a nuclear protein whose exact biological function remains unknown. It has been suggested that it is important for DNA repair, (48) and through its interaction with several proteins involved in transcription and mRNA processing it may also play a role in coordinating transcriptional events and in splicing regulation (49).

### 132.7.4 ALS 5 or Spatacsin-Linked ALS

Linkage of an autosomal recessive, slowly progressive, juvenile ALS or ALS5 was linked by Hentati and colleagues in 1998 to chromosome 15q15–q22 (50). Mutations in the *spatacsin* gene were identified by Orlacchio et al. in 2010 in 10 out of the 25 families studied with autosomal recessive juvenile onset ALS (51). The

*spatacsin* gene was previously reported to cause autosomal recessive spastic paraplegia with thin corpus callosum or SPG11 (52). The function of the protein is currently undetermined.

### 132.7.5 ALS6 or Fused in Sarcoma, Translocated in Liposarcoma (FUS/TLS)-Linked ALS

Mutations in *FUS/TLS* were initially reported independently but simultaneously by two groups of investigators in 2009. Kwiatkowski et al. reported 13 mutations in *FUS/TLS* in 17 different familial ALS kindreds linked to chromosome 16 or ALS6 (53) and Vance et al. reported 3 *FUS* mutations in nine additional families with ALS6 (54). Since these reports, about 35 pathogenic mutations have been reported to date in about 4% of all familial ALS and 5% in non SOD1-ALS and non TARDBP-ALS; however *FUS/TLS* mutations are rare (less than 1%) in sporadic patients with no apparent family history (55–57). It appears to be the second most frequent cause of familial ALS after SOD1. The inheritance pattern is dominant, except for one recessive mutation found in a family of Cape Verdean origin (53). Most mutations are missense mutations, except for few in-frame or frame-shift deletions or insertions, and all seem to cluster in exons four to six and 13 to 15 of the gene (55,57). Mutations in *FUS/TLS* are not restricted to any ethnic group, since they were found in European, African, Australian, European American, African American, Asian and Latino subjects (53–55,58–60).

Most patients with *FUS/TLS* mutation develop the classic ALS phenotype without cognitive impairment. In the series reported by Yan et al. patients with *FUS/TLS* had earlier age of onset, a higher rate of bulbar onset, and a shorter duration of symptoms than FALS patients with the SOD1 mutation (55). Other groups reported an atypical phenotype that consisted of symmetric proximal and axial weakness at onset with and without bulbar signs (58,61,62). About four *FUS/TLS* mutations have been associated with either FTD/MND or behavior variant FTD (55,61,63,64), and one mutation (R521C) was reported in an ALS/PD/DE complex index case (55). It is interesting that the R521C mutation is the most common *FUS/TLS* mutation reported and is also the one associated with atypical presentations.

*FUS/TLS* is a ubiquitously expressed 526 amino acid protein, encoded by 15 exons (65). *FUS/TLS* was initially isolated from the specific chromosomal translocation breakpoint of mixoid liposarcoma as the 5' part of a fusion gene with the transcription factor gene *CHOP* (66,67). *FUS/TLS* predominantly localizes to the nucleus and belongs to the FET/TET family of RNA/DNA binding proteins, together with Ewing's sarcoma protein (EWS) and the TATA-binding protein associated factor (TAF 15) (57,68).

The protein is characterized by an N-terminal domain rich in glutamine, glycine, serine and tyrosine residues, a glycine-rich region, an RNA recognition motif (RRM), multiple arginine/glycine/glycine (RGG) repeat in an arginine- and glycine-rich region and a C-terminal zinc finger motif (69–71). As in ALS caused by *TDP43* mutations, most ALS-causing mutations are clustered in the glycine-rich region and in the extreme C-terminal part of the protein. *FUS/TLS* was found to be essential for mice neonatal viability, since disruption of this gene in mice caused death of the animal within 16 h of birth (72). *FUS/TLS* is structurally close to the family of heterogeneous ribonucleoproteins (hnRNPs). It interacts with RNA, single and double stranded DNA, and is involved in a wide range of RNA-related cellular processes including transcription, pre-mRNA splicing, mRNA transport from nucleus to cytoplasm and micro RNA processing (55,56). *FUS/TLS* was found in RNA-transporting granules translocating to dendritic spines under excitatory stimulation (73). Cultured hippocampal neurons from *fus/tls* knockout mice displayed abnormal spine morphology and density, indicating that *FUS/TLS* participates in mRNA sorting to the dendritic spines and may regulate spine morphology to stabilize the synaptic structure (73). *FUS/TLS* is also a component of RNA stress granules (74).

Spinal cord sections from ALS patients with the *FUS/TLS* mutation show ubiquitin and p62 immunopositive skein-like cytoplasmic inclusions that are negative for *TDP43* but immunoreactive for *FUS/TLS* (54). *FUS/TLS* inclusions were initially only found in FALS patients with *FUS/TLS* mutations (53,54). Using a high pressure decloaking chamber technique for antigen retrieval, Deng et al. demonstrated that cytoplasmic *FUS* immunoreactive inclusions are not restricted to FALS due to *FUS* mutations, but were also found to colocalize with *TDP43*, ubiquitin and p62 in sporadic ALS, ALS/dementia, familial ALS due to *TDP43* and in non-SOD1 familial ALS tissue. Similar to *TDP43* inclusions, *FUS* immunopositive inclusions were absent in SOD1-linked ALS (23). *FUS* immunoreactive inclusions were also found in a subset of *TDP43* negative FTL-D-U cases (75), neuronal intermediate filament inclusion disease (76) and basophilic inclusion body disease (77).

How mutations in *FUS/TLS* cause disease remains poorly defined, but the discovery of *TDP43* and *FUS/TLS* mutations in familial ALS in RNA-DNA binding proteins shifted the focus of research to the role of RNA metabolism and processing in the pathogenesis of ALS.

### 132.7.6 ALS8 or Vesicle-Associated Membrane Protein-Associated Protein B: VAPB-Linked ALS

In a large Brazilian family of Portuguese extraction with autosomal dominant, slowly progressive, lower motor neuron disease or ALS8, Nishimura et al. established

linkage to chromosome 20q13 (78) and subsequently reported a missense P56S mutation in a vesicle-associated membrane protein-associated protein B gene (*VAPB*) in this family and in six additional families of the same heritage (79). This mutation resulted in three different clinical phenotypes: late onset SMA of Finkel Type, late onset, slowly progressive, atypical ALS with essential tremor, and typical ALS. Haplotype analysis of these seven families and a further Brazilian family of African origin showed a common founder effect arising around the middle of the fifteenth century at the time of Portuguese immigration to South America (80). This mutation has since been reported in two additional Brazilian families (81,82). The *VAPB* P56S mutation was also recently reported in a familial ALS patient of Japanese descent (60).

More recently a new missense mutation T46L was reported in a non-Brazilian familial ALS patient (83). Although segregation of this mutation with the disease phenotype in this family could not be demonstrated due to non-availability of DNA, functional *in vitro* and *in vivo* studies strongly suggest a pathogenic role for this mutation (83).

The *VAPB* gene contains six exons and encodes a 243 amino acid protein that is highly conserved and ubiquitously expressed. It contains three domains: a conserved N-terminal MSP (major sperm protein) domain shared by other vesicle-associated membrane proteins, a coiled-coil t-SNARE homology domain and C-terminal transmembrane domain (84). It is an intracellular membrane protein that is enriched in the endoplasmic reticulum and Golgi membranes; it is involved in the recruitment of FFAT motif containing proteins to the ER (85), vesicle trafficking (86), and plays a role in the unfolded protein response (87). In *Drosophila*, the fly homolog of *VAPB* binds to microtubule network and regulates bouton size at the neuromuscular junction (88). Introduction of the P56S mutation in cell cultures causes *VAPB* to lose its normal ER association and form dense cytoplasm aggregates (79,87). Many *Drosophila* models carrying either a P56S or a T46L corresponding mutation have been generated; they recapitulate many aspects of the disease, with a motor phenotype, neuronal cell death and aggregate formation (83), (89–91). The exact role of the *VAPB* mutation in motor neuron degeneration remains a mystery. Aside from its role in vesicular trafficking and the unfolded protein response, *VAPB* interaction with lipid binding proteins adds lipid metabolism dysfunction to the pathogenesis of ALS.

### 132.7.7 ALS9 or Angiogenin-Linked ALS

Greenway and colleagues established chromosome 14q11 as a new candidate region for autosomal dominant familial ALS or ALS9, and identified mutations in the Angiogenin gene in four familial and 11 sporadic ALS patients, mostly of Irish or Scottish descent (92,93).

Angiogenin gene mutation has since been reported in sporadic and familial patients from North America, France, Germany and Italy (60,94,95).

The Angiogenin gene (*ANG*) encodes a 14-kD angiogenic ribonuclease, a hypoxia responsive gene and a potent inducer of neovascularization in vivo. Wild type angiogenin was demonstrated to protect motor neurons from hypoxia-induced cell death, (96) and all the ALS-associated mutations showed a reduced neuroprotective activity against hypoxic injury, suggesting that angiogenin may be implicated in ALS pathogenesis through a loss of function (97).

### 132.7.8 ALS10 or TAR-DNA Binding Protein 43-Linked ALS

The identification of TAR-DNA binding protein 43 (TDP43) as the major disease protein of the ubiquitinated inclusions in ALS and in Frontotemporal lobar degeneration with ubiquitinated inclusions (FTLD-U) (12) led many authors to investigate the role of TDP43 in ALS pathogenesis, and to screen patients with familial ALS for mutations in the *TARDBP* gene. Sreedharan et al. screened 154 index familial ALS cases for mutations in *TARDBP*; they identified the M337V mutation in exon six of *TARDBP* gene in five affected individuals (four males and one female) from a two generation Caucasian family of English descent (98). They subsequently sequenced all six exons of *TARDBP* in a cohort of 200 British patients with sporadic ALS and identified another missense mutation, Q331L, in a man with limb onset ALS at the age of 72. No *TARDBP* mutation was found in a screen of 500 British controls. Screening of all six exons in an Australian sporadic ALS cohort identified a third mutation: G294A in a patient with limb onset ALS that started at the age of 65, with disease duration of 5 years (98). Since that report, a total of 38 mutations have been described in ALS patients with or without family history of ALS, corresponding to about 4% of familial ALS and about 1% of sporadic ALS cases (56). Most of the identified mutations are localized in the glycine rich region encoded by exon 6. They are all dominant missense mutations except for Y374X, a truncation at the extreme C-terminal of the protein (56). Most patients with *TDP43* mutations develop a classic ALS phenotype with bulbar or limb onset and without cognitive deficit. A few *TARDBP* mutations, some in exon 6, have also been identified in patients with behavior variant FTD or in FTD-MND (99,100) validating the fact that *TARDBP* mutations are not restricted to ALS alone.

The *TARDBP* gene is located on chromosome 1 (1p36), contains six exons and encodes the 43-kD TAR DNA-binding protein. Through alternative splicing, this gene could express 11 and may be more isoforms (101).

TDP43 belongs to the family of heterogeneous nuclear ribonucleoproteins (hn RNP) that bind RNA and DNA sequences through a common nucleotide binding domain

known as the RNA recognition motif (102). TDP43 is ubiquitously expressed, highly conserved throughout species (102) and predominantly localized to the nucleus (103). TDP43 was initially identified as the protein that binds specifically to pyrimidine-rich motifs of regulatory element in the HIV-1 long terminal repeat (LTR) known as TAR, and modulates HIV gene expression (104). TDP 43 is also involved in the regulation of Cystic Fibrosis Transmembrane Conductance Regulator (CFTR) exon 9 splicing (105). The protein is composed of two RNA recognition motifs (RRM1 and RRM2) flanked by an N-terminal and a C-terminal tail. The C-terminal region contains the glycine-rich domain that is important for protein-protein interaction (106) and the exon skipping activity of TDP43 (101). TDP43 is involved in many biological functions such as transcription and splicing regulation, mRNA stability (106) and micro RNA processing (107). TDP43 was also recently demonstrated to have multiple roles in the regulation of mRNA fate in neuronal cells, such as transcript stabilization and activity-dependent transport to dendrites (108,109).

TDP43 is also capable of responding to an environmental insult by assembling into stress granules (SGs), which are cytoplasmic ribonucleoprotein foci that sequester mRNAs, several RNA binding proteins and stalled translation initiation complexes to temporarily arrest protein synthesis as a protective response to cellular stress (110). In axotomized motor neurons in vivo, TDP43 was found to translocate to the cytoplasm, where it formed stress granules that dissolved after recovery, suggesting a role for TDP43 in shuttling mRNA between the nucleus and cytosol, during acute neuronal injury (111).

To investigate the role of TDP 43 in the pathogenesis of ALS several cell and animal models were developed:

Homozygous knock-down of *tdp43* is embryonically lethal in mice. Heterozygous *tdarbp* mutant mice exhibit signs of motor disturbance and muscle weakness without pathological changes in motor neurons (112). Knock-down of zebra fish *tdarbp* led to swimming deficit, which was rescued by co-expressing wild type, but not mutant, human *TARDBP* (113).

Overexpression of wild type *TDP43* in a transgenic mouse line led to a dose-dependent degeneration of cortical and spinal motor neurons and the development of spastic paraparesis reminiscent of ALS (114). Affected neurons showed accumulation of ubiquitinated and phosphorylated nuclear and, to a lesser degree, cytoplasmic TDP43 aggregates. The characteristic ~25-kDa C-terminal fragments were recovered from nuclear fractions and correlated with disease development and progression in wild-type TDP43 mice. Expression of human *TDP43* in various neuronal sub-populations of *Drosophila* also caused neurodegeneration, in particular expression in motor neurons led to motor neuronal loss with decreased locomotive abilities in the fly (115).

Overexpression of wild type or mutant *TDP43* in primary rat cortical neurons was toxic to primary neurons

and resulted in cytoplasmic mislocalization of the protein TDP43 (116). When mutant (A315T) *TDP43* was overexpressed in mice, it caused a progressive and fatal neurodegenerative disease reminiscent of ALS and FTLD-U without the presence of cytoplasmic TDP43 aggregates (117). In rats, however, overexpression of mutant *TDP43* (M337V) caused widespread neurodegeneration that predominantly affected the motor system, with degeneration of motor neurons and denervation atrophy of skeletal muscles recapitulating the ALS phenotype, with formation of cytoplasmic TDP 43 inclusions (118). Mutant *TARDBP* also caused a motor phenotype in zebrafish associated with shorter and disorganized axons with excessive branching as well as swimming deficits (113).

As stated above, in most cases of sporadic ALS and FALS due to *TDP43* mutation, the neuropathology is characterized by abnormal cytoplasmic accumulation of TDP43 that is associated with the formation of intracellular aggregate in the affected areas in these patients together with a reduction in the normal nuclear staining (57). In these aggregates TDP43 is phosphorylated, ubiquitinated and cleaved forming the 20–25 kDa C-terminal fragment that accumulates in detergent insoluble fractions derived from patients' tissues (12). Although it is clear from the animal models that TDP 43 is involved in neurodegeneration, the exact mechanism of TDP 43-induced neurodegeneration is yet to be resolved. Whether the toxicity of TDP 43 arises from the aggregate formation and the sequestration of essential proteins causing a toxic gain of function versus loss of its nuclear function or both is still debatable.

### 132.7.9 ALS11 or FIG4-Linked ALS

Mutations of the human *FIG4* gene on chromosome 6q21 are responsible for the recessively inherited disorder CMT4J, a severe early onset form of Charcot-Marie-Tooth disease. Chow et al. sequenced the *FIG4* gene in sporadic and familial ALS, and identified ten unique heterozygous variants of *FIG4* in nine patients: six with sporadic ALS and three with familial disease. These patients had upper motor neuron-predominant ALS of long duration and two patients had PLS (119). *FIG4* is a phosphoinositide 5-phosphatase that regulates the cellular abundance of phosphatidylinositol 3,5-bisphosphate. Phosphoinositides serve as molecular tags for intracellular vesicles and mediate vesicle trafficking. The etiological or pathogenic role of *FIG4* mutations has not been established.

### 132.7.10 ALS12 or Optineurin-Linked ALS

Maruyama et al. identified three mutations in the Optineurin (*OPTN*) gene in Japanese patients with familial or sporadic ALS (120). In four Japanese individuals from consanguineous families with ALS (ALS12) they found two homozygote mutations in the *OPTN* gene, one a

deletion of exon 5 in two siblings and the other a nonsense mutation (Q398X) in exon 12 in two individuals thought to be unrelated but who shared a common haplotype for a 0.9-Mb region containing the *OPTN* gene (120). They also found a heterozygous missense mutation (E478G) in exon 14 of *OPTN* gene in four individuals from two families with ALS. Although the inheritance pattern appeared to be autosomal dominant with incomplete penetrance, all affected individuals shared a common haplotype for 2.3 Mb on chromosome 10 around the *OPTN* gene suggesting a common founder effect.

Mutations in the *OPTN* gene were previously reported to cause primary open angle glaucoma and normal tension glaucoma (121). Both Q398X and E478G mutations were absent in a total of 5000 Japanese chromosomes, including subjects from the glaucoma study. The deletion mutation was also absent in 200 Japanese subjects, and not reported in over 6000 glaucoma individuals (120).

*OPTN* contains three noncoding exons in the 5'-untranslated region (UTR) and 13 exons that code for a 577-amino acid protein (121). It is a conserved protein that contains multiple coiled-coil domains, a leucine zipper, a ubiquitin-binding domain and a C<sub>2</sub>H<sub>2</sub> type zinc finger at its C-terminus (122). Although optineurin is ubiquitously expressed, it shows particularly high level of expression in certain tissues such as the retina, brain, heart, skeletal muscle, placenta, testis and kidney. Studies in various cell lines have shown that endogenous optineurin is present in the cytoplasm, Golgi and recycling endosomes (122).

Optineurin was first discovered as a binding partner of the adenoviral protein E3-14.7K and was shown to protect infected cells from TNF- $\alpha$ -induced cytolysis (123).

Optineurin shares a 53% amino acid homology with NF- $\kappa$ B essential modulator and was identified as an NF- $\kappa$ B essential modulator-related protein (124). It has been recently shown that *OPTN* is a negative modulator of NF- $\kappa$ B (125). *OPTN* links myosin VI to the Golgi complex and is involved in Golgi organization and exocytosis (126). It also interacts with Rab 8 and huntingtin and seems to be involved in the endosomal trafficking of the transferrin receptor (122).

The ability of optineurin to negatively modulate the NF- $\kappa$ B activity was lost when mouse neuroblastoma and spinal cord hybrid cell lines were transfected with Q398X and E478G mutant *OPTN* but not when transfected with wild type or glaucoma causing mutation in *OPTN* (120). Examination of the spinal cord from the subject with the E478G mutation, revealed intracytoplasmic eosinophilic inclusions in the motor neurons that were immunopositive for *OPTN*. Positive optineurin inclusions were also found in TDP43 and ubiquitin positive inclusions in patients with sporadic ALS. The SOD1-immunopositive Lewy body-like hyaline inclusions from cases with SOD1 linked familial ALS were also immunoreactive for optineurin (120).

It has been recently reported that optineurin positive inclusions are not restricted to ALS but have also been found in the ubiquitin-positive intraneuronal inclusions in ALS with dementia, in basophilic inclusions in the basophilic type of ALS, in neurofibrillary tangles and in dystrophic neurites in Alzheimer's disease, in Lewy bodies and in Lewy neurites in Parkinson's disease, in ballooned neurons in Creutzfeldt–Jakob disease, in glial cytoplasmic inclusions in multiple system atrophy, and in Pick bodies in Pick disease (127). Recently OPTN immunoreactive skein-like inclusions were found in the motor neurons from post-mortem spinal cords of patients with sporadic ALS and familial ALS without SOD1 mutations, but not in SOD1-linked ALS, or in the transgenic mice over-expressing SOD1<sup>G93A</sup> or SOD1<sup>L126Z</sup> (128). This finding implicates OPTN together with TDP43 and FUS in the pathophysiology of sporadic ALS and familial ALS not linked to SOD1. The exact role of OPTN in ALS is not known and, similar to TDP43 and FUS, could be related to a loss of function because of the sequestration of the protein in the inclusions or could be due to a toxic gain of function. Recently and most importantly, phosphorylated optineurin has been associated with autophagy; an emerging theme in neurodegeneration (147).

### 132.7.11 D-Amino Acid Oxidase ALS Linked to Chromosome 12q22

In a three generational familial ALS kindred with classic adult onset autosomal dominant ALS, Mitchell et al. reported an R199W mutation in the D amino acid oxidase gene (*DAO*). They demonstrated that this disease-associated mutation causes almost total loss of enzyme activity, impairs cell viability, promotes the formation of ubiquitin aggregates and increases apoptosis in neuronal cells (129). DAO is a peroxisomal flavoenzyme that catalyzes the oxidative deamination of D-amino acids such as D-alanine, D-serine, and D-proline to their corresponding keto-acids. In the brain, DAO controls the level of D-serine, a potent activator of N-methyl-D-aspartate-type glutamate receptor enhancing glutamate transmission that was shown to be elevated in the spinal cord of ALS patients and G93A transgenic mice (130).

### 132.7.12 Valosin-Containing Protein (VCP)-Linked ALS

Using whole exome sequencing, Johnson et al. recently reported five mutations in the *VCP* gene in patients with autosomal dominant familial ALS not linked to *SOD1*, *FUS* or *TDP43* (131). Two of these mutations (R191Q and R155H) were previously reported to cause Inclusion Body Myositis associated with Paget's disease of the bone and Fronto-Temporal Dementia (IBMPFD). The original IBMPFD was examined by one of us and no evidence of IBM was found; instead, greater proximal than

distal atrophy of spinal innervated muscles and respiratory failure was noted, along with mixed myopathic and neuropathic features on EMG (Siddique, unpublished). The obligate carrier of the R155H mutations comes from a large multigenerational family with IBMPFD and had a clinical diagnosis of ALS that was confirmed pathologically. In the nine reported patients with *VCP* mutation, three had dementia and five had rapid disease progression. Except for the family with the R155H mutation and one other relative of a patient with R191Q mutation that had bone disease, none had any personal or family history of muscle or bone disease.

*VCP* is a highly conserved, ubiquitously expressed, 97kDa protein that is a member of the AAA+ protein family of ATPases or ATPases associated with diverse cellular activity. These proteins are characterized by the presence of two ATPase domains, called the AAA domain. They are enzymatic machines that catalyze ATP hydrolysis and mediate many cellular functions, such as vesicle transport, organelle assembly, membrane dynamics and protein unfolding (132). Dysfunction in this family of proteins has been already implicated in hereditary spastic paraparesis due to spastin and paraplegin mutation.

The *VCP* protein has an N-terminal domain and two central D1 and D2 AAA+ domains. The N-terminal domain is necessary for substrate and cofactor association, whereas the D1 and D2 domains are needed for ATP binding and hydrolysis. A *VCP* monomer assembles into a functioning stable homo-hexamer with a central cylinder formed by the D1/2 domains surrounded by the N domains (133).

*VCP* has diverse biological functions. *Vcp* knockout is lethal in yeast, *C. elegans* and mice. It associates with many members of the ubiquitin-proteasome system, it is essential for endoplasmic reticulum associated degradation of misfolded ER, transmembrane and secreted proteins, (134) and participates in the delivery of degradation destined ubiquitinated cytosolic proteins to the 26S proteasome (135). *VCP* is also essential for autophagosome maturation and might be selectively required for autophagic degradation of ubiquitinated proteins, since overexpression of IBMPFD associated *VCP* mutation (R155H and A232E) in cells caused autophagy defect and accumulated autophagic vesicles contain ubiquitin-positive contents (136). *VCP* is now thought to be important for the coordination of protein degradation by both the ubiquitin-proteasome system and autophagy (133).

In normal muscle, *VCP* stains endomysial vessels and to a mild degree, muscle fiber's cytoplasm. In sporadic IBM, *VCP* staining was localized to debris in inclusions and vacuoles, but there was considerable staining in inflammatory cells and in regenerating muscle fibers. In muscles with IBMPFD, *VCP* was localized in large or small rounded aggregates in scattered muscle fibers, including those with no clear vacuoles or other

morphological changes (137). Patients with VCP dementia have ubiquitin positive intranuclear neuronal inclusions and rare intranuclear neuronal VCP inclusions (138,139). Both brain and muscle tissues from patients with IBMPFD showed the presence of TDP43 inclusions that co-localized with ubiquitin (138). Similar to Optineurin, VCP immunoreactivity was also observed in ubiquitin-positive intraneuronal inclusions in motor neuron disease with dementia, ballooned neurons in CJD, dystrophic neurites of senile plaque in Alzheimer's disease, and Lewy bodies in Parkinson's disease, thus implicating VCP in a wide array of neurodegenerative diseases.

The role of VCP in ALS pathogenesis is unclear, and according to Johnson et al., is responsible of about 1–2% of familial ALS, which is similar to that reported for TDP43. The discovery of VCP mutations causing ALS underscores the role of protein homeostasis, and the interface between the proteasomal system and autophagy in the pathogenesis of ALS, although the role of VCP in the proteasomal system is controversial.

### 132.7.13 ALS-FTD Linked to Chromosome 9p21

Many authors reported autosomal dominant familial ALS and frontotemporal dementia where motor neuron disease and the dementia exist as a spectrum with significant interfamilial variability (140–143).

Linkage analysis of our families with FTD-ALS revealed a LOD score of nine on chromosome 9p21 with a minimal candidate region of 3 megabases. We identified 8 KB of common disease haplotype in three of these families (Siddique unpublished). This locus was recognized as a major locus for FTD-ALS by several investigators (140,141,144).

Recently, two independent research teams reported the presence of a hexa-nucleotide repeat expansion GGGGCC located between non-coding exon 1a and exon 1b of *C9ORF72* gene that segregate with disease phenotype in FTD-ALS kindred (145,146).

*C9ORF72* is a gene that encodes an uncharacterized protein with no known domain or function but which is highly conserved across species. At least three alternatively spliced transcripts are expressed in all tissues, including the brain (146). The non-coding repeat expansion may act pathologically by reducing the translation of the *C9ORF72* long transcript or by sequestering RNA binding proteins, leading to dysregulation of alternative mRNA splicing as in myotonic dystrophy or in several spinocerebellar ataxias (146).

The neuropathology of familial ALS/FTD linked to chromosome 9p is characterized by the presence of ubiquitin and TDP43 immunoreactive neuronal cytoplasmic inclusions in the frontal cortex, dentate gyrus of the hippocampus and the hypoglossal nucleus (57,144). It is also interesting that hippocampal sections of patients

with ALS/FTD displayed prominent ubiquilin2 pathology (147). These ubiquilin2 inclusions were positive for ubiquitin and p62 but for the most part negative for TDP43 (147).

### 132.7.14 X-ALS or ALS/Dementia Linked to Ubiquilin2 Gene or *UBQLN2*

In a five generation family with X-linked dominant ALS and 19 affected individuals, we established linkage to a 21.3 Mb minimum candidate region on Xp11.23. Sequence analysis of 41 genes in the region revealed a missense mutation in *UBQLN2* gene which encodes ubiquilin2 in this X-ALS family. Four other *UBQLN2* mutations were also discovered in four unrelated families with ALS or ALS/dementia but without male-to-male transmission. None of these mutations were present in the SNP database or in the 928 ethnically matched control samples (147).

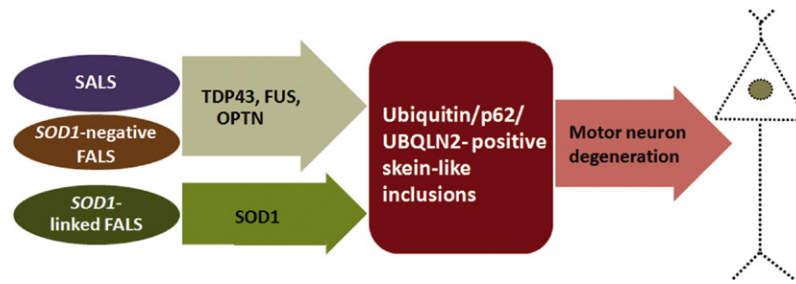

Clinically, patients presented with ALS or with ALS/dementia of the FTD variant. Age of disease onset was significantly younger in males compared to females, whereas disease duration was similar. Autopsy data were available from three patients with *UBQLN2* mutations. Pathological analysis of the spinal cord showed axonal loss in the corticospinal tract, loss of anterior horn cells and astrocytosis. Ubiquilin2 immunoreactive skein-like inclusions were observed in some remaining motor neurons. These inclusions were also immunopositive for ubiquitin, P62, TDP43, FUS and optineurin, but not for SOD1. The ubiquilin2-positive inclusions were also found in spinal cord sections of patients with sporadic ALS, ALS with dementia and FALS without SOD1 mutations (Figure 132-1). Spinal cord sections from patients with familial ALS due to SOD1 mutations did not show ubiquilin2-positive inclusions (Figure 132-1), supporting the hypothesis that SOD1-linked ALS has an independent pathway from the other forms of ALS (Figure 132-2) (147).

Apart from the spinal cord, widespread ubiquilin2-positive inclusions were also observed in the hippocampus of the ALS patients with dementia (Figure 132-3). But ALS patients without dementia did not show ubiquilin2-positive inclusions in the hippocampus, thus linking the hippocampal ubiquilin2 pathology to the cognitive decline in ALS patients with dementia.

Ubiquilin2 is one of the four members in the Ubiquitin-like protein family that functionally link the ubiquitinated proteins to the protein degradation machinery (148,149). Expression of mutant ubiquilin2 results in an impairment of ubiquitinated protein degradation. These data, therefore, link mutations of ubiquilin2 to defects in the protein degradation pathway, abnormal protein aggregation and neurodegeneration, implying a common pathogenic mechanism underlying degeneration processes, not only in motor neurons but also other neurons as well (Table 132-1) (147).

**FIGURE 132-1** Differential involvement of ALS-associated proteins in skein-like inclusions in different types of ALS. Confocal microscopy was performed using immunofluorescent staining of the spinal cord sections from autopsy cases with sporadic and SOD1-linked ALS or a SOD1-ALS mouse model. Representative skein-like inclusions are shown to be immunoreactive for TDP43, FUS and ubiquilin2 in sporadic ALS (a–i). TDP43 is negative in the SOD1-positive inclusions in SOD1-linked ALS (j–l). However, skein-like inclusions are positive for ubiquilin2 in an ALS mouse model expressing mutant SOD1 (m–o). SALS, sporadic ALS; SOD1-A4V, ALS case with an A4V mutation of SOD1; SOD1-L126Z-tg, transgenic mouse expressing L126Z mutation of SOD1.

**FIGURE 132-2** Schematic model depicting two parallel pathways involved in the pathogenesis of ALS. UBQLN2, TDP43, FUS and optineurin are components of pathological inclusions in SALS and *SOD1*-negative FALS including *C9ORF72*-linked cases. *SOD1* aggregates are predominantly present in *SOD1*-linked FALS. The involvement of ubiquitin, p62 and ubiquilin2 may occur downstream and lead to formation of skein-like inclusions and ultimately motor neuron degeneration.

**FIGURE 132-3** Ubiquilin2 pathology in the hippocampus of ALS/dementia cases with or without UBQLN2 mutation. Confocal microscopy was performed using immunofluorescent staining of the hippocampal sections from an autopsy case with a UBQLN2-P506T mutation (a–f) and an ALS/dementia case without a UBQLN2 mutation (g–l). Representative neuritic inclusions that are ubiquilin2-positive, but TDP43-negative in the molecular layer of the dentate gyrus (DG) and CA region (CA) are indicated by arrows (a–f). Representative Neuritic and cytoplasmic ubiquilin2-positive inclusions in the molecular layer and dentate granule cells of the dentate gyrus (g–i), and CA region (j–l) are indicated by arrows and arrowheads, respectively.

### 132.8 GENETICS OF SPORADIC AMYOTROPHIC LATERAL SCLEROSIS

Although the etiology of sporadic ALS is currently unknown, it is believed that the disease may arise from complex interactions between susceptibility genes and diverse environmental factors. Exploring the genetic basis of sporadic ALS and identifying these susceptibility genes has been a hot topic these past years, as the genes may provide clues to specific pathogenic pathways or indicate specific environmental risk factors.

The modern tools of molecular genetics has facilitated the genotyping of hundreds of thousands of single nucleotide polymorphisms (SNP) in each sample and allowed us to perform association studies using population-based case-control samples or family-based samples to determine whether a specific DNA sequence change will be found more frequently in disease cases than in controls.

To date, twelve genome-wide association studies (GWAS) and several candidate gene association studies have been published regarding sporadic ALS, with the first reported in 2007 (150). All these studies were hindered by the need for a large sample size; the small odds ratio measured that usually did not survive Bonferroni correction and the inability to replicate the results in different populations. Most samples were not matched to controls.

Nevertheless, these studies have revealed interesting genetic associations with sporadic ALS:

- FLJ10986 or FGGY was the first potential candidate gene to be discovered in a US population. It codes for a protein of unknown function that is expressed in the spinal cord and spinal fluid of patients and controls (151). Certain SNPs seemed to be associated with sex, age at onset, and site of onset of sporadic ALS. An SNP in this gene was also found to increase ALS susceptibility in a Chinese population (152); however, these findings were not replicated in a homogenous population from Northern Europe (153), from Germany (153), nor in a French or French Canadian cohort (154).
- ITPR2, or inositol 1,4,5-triphosphate receptor 2 gene, which encodes a calcium channel on the endoplasmic reticulum that is primarily responsible for controlling intracellular calcium concentrations in neurons, was identified as a susceptibility gene in a Dutch GWAS study that was replicated in Swedish and Belgian population with higher peripheral blood expression of ITPR2 in ALS patients compared to controls (155). Again these findings were not replicated in other GWAS studies involving individuals of European ancestry (156,157).

- DPP6 encodes a dipeptidyl-peptidase-like protein and was identified as a susceptibility gene in different populations of European ancestry (158). The identified variant was subsequently confirmed in two further cohorts of 221 Irish and 266 Italian sporadic cases (159,160) but failed to be replicated in additional Irish and Polish populations (161) and in a large two-stage GWAS of more than 2000 cases of US, Italian and German background (157) or in a large independent Italian population (162).

A recent study of more than 19,000 patients from nine countries identified an SNP in the UNC13A gene as being strongly associated with sporadic ALS (163). Members of the UNC13 family, such as UNC13A, are presynaptic proteins found in central and neuromuscular synapses that regulate the release of neurotransmitters (163). This SNP, however was not confirmed in an independent French population (164).

The Van ES study also identified 9p21 as susceptibility locus for sporadic ALS (163); this finding was also confirmed in another GWAS study including samples from the UK, USA, Netherlands, Ireland, Italy, France, Sweden and Belgium (165). In this last study, none of the previously associated SNPs in ITPR2, FGGY in DPP6 and in UNC13A reached genome-wide significance (165). Replication of the study of the two genetic variants, rs2814707 on 9p21.2 and rs12608932 on 19p13.3 that were reported to be most significantly associated with sporadic amyotrophic lateral sclerosis by van ES showed no evidence of association in Chinese and Japanese populations (166).

A Finnish GWAS study using familial and sporadic ALS samples and controls also found strong association with the 9p locus in the ALS patients; however the association was driven mainly by the familial cases and was much weaker in the sporadic cases (167). Although these findings suggest that the locus on 9p might be important not only to familial ALS-FTD but also for sporadic ALS, caution should be used in the interpretation of these results as it is not clear how careful the investigators were in excluding familial cases. Our study, using 500 sporadic ALS and 500 controls, did not reveal any association with the chromosome 9p locus for any single SNP; however haplotype analysis showed a robust association with the following SNPs: rs2814707, rs3849942 and rs903603 (Siddique, data not published).

In a pooled set of patients with ALS and controls from the UK, US and Belgium, the allelic variants of the RNA polymerase II component, ELP3, was found to be associated with ALS (168). Zebrafish knock down of ELP3 showed abnormal axonal branching similar to overexpression of SOD1 and knock down of ALSIN in zebra fish.

A candidate gene association approach was also used to investigate the role of several genes in sporadic ALS, such as APEX, VEGF, SMN1 and SMN2

copy numbers, HFE, DNCT1 and NEFL, with variable results or a mildly increased risk that was not replicated in repeat studies. These genes did not show any association in genome-wide association studies. A variant of the Angiogenin gene was associated with an increased risk of ALS in the Irish and Scottish population, (92) and mutations in these genes were found in sporadic and familial patients of Irish and Scottish descent (93). Peripherin gene mutations have been identified in two sporadic ALS patients, but it is not clear whether these variants are disease-causing or rare polymorphisms (169). Studies of APOE provided conflicting results: the E2 allele was shown to protect against early onset ALS (170), whereas the E4 allele may increase the risk of bulbar onset ALS in men (171). More recently, Ataxin-2 intermediate-length polyglutamine expansions were found to be associated with increased risk of ALS (172,173).

The paraoxonase (PON) gene cluster on chromosome 7q21 has been extensively examined in the past years, and has emerged as the most robust genetic risk factor for ALS. The PON genes, PON1, PON2 and PON3, code for enzymes involved in the detoxification of organophosphate pesticides and chemical nerve agents. A haplotype of large linkage disequilibrium spanning PON2 and PON3 was found to be associated with sporadic ALS in a large North American Caucasian family-based and case control cohort (174). Association with PON genes was also reported in Polish, Irish, French, French Canadian and Swedish populations (175–177). Seven missense mutations in the PON1 gene were identified in sporadic and familial ALS patients that were predicted to alter PON function, (178) further implicating the PON genes in the pathogenesis of ALS. It is of interest that mutation in a gene of similar function to PON (neuropathy target esterase (NTE)) causes autosomal recessive spastic paraplegia with distal muscle wasting, resembling Troyer Syndrome.

Lastly, Fecto et al. recently reported 10 heterozygote mutations in the P62 or Sequestosome1 (SQSTM1) gene in six individuals with familial ALS and in nine sporadic patients (179). These changes were absent in 724 controls, in the SNP database and in the 1000 genome database. Segregation studies were not performed due to a lack of DNA and predictive *in silico* analysis classified these mutations as pathogenic (179).

P62 is located on chromosome 5q35 and has eight coding exons. The protein is ubiquitously expressed, highly conserved in mammals, and has many functional domains (180). P62 plays an important role in protein degradation through the proteasomal pathway and the autophagic/lysosomal pathway (181,182). It is present in neuronal and glial ubiquitinated inclusions of many neurodegenerative diseases such as Alzheimer's, Parkinson's disease, and Dementia with Lewy bodies (183). It co-localizes with FUS and TDP43 in

ubiquitinated inclusions in the spinal motor neurons of sporadic ALS, non-SOD1 familial ALS and ALS with dementia (23,184).

It is of interest that three of the reported mutations located in the UBA domain have been previously identified in familial and sporadic Paget's disease of bone (185). We already know that at least two other genes, VCP and Optineurin, have been genetically linked to both ALS and Paget's disease of bone, suggesting that there might be a unifying point in the pathogenesis of the two diseases.

### 132.8.1 Amyotrophic Lateral Sclerosis and Parkinsonism Dementia Complex

Amyotrophic lateral sclerosis-parkinsonism/dementia complex of Guam is a fatal neurodegenerative disorder with unusually high incidence among the Chamorro people of Guam, in the Kii peninsula of Japan and in New Guinea. Clinically this syndrome is characterized by the co-occurrence of ALS with rigido-akinetic parkinsonism and early and severe dementia (186). Pathologically this syndrome is distinguished from classic ALS by the presence of widespread neurofibrillary tangles in the brain and in the spinal cord (186). The incidence of this disease was highest in the 1950s and has been in steady decline in the past decades. The familial clustering of ALS/PDC suggested a genetic basis for this syndrome early on, and segregation analysis supported an autosomal dominant inheritance with reduced penetrance that is possibly affected by environmental factors (187). No major locus for ALS/PDC has been identified; however a recent genome wide linkage analysis of a large complex pedigree and a series of smaller families from Guam, and a genome wide association analysis of Chamorro-based cases and controls revealed a strong association with three loci; two on chromosome 12 and one on chromosome 17 close to the MAPT locus (188).

### 132.8.2 Clinical Approach to the Genetic Diagnosis or Genotype–Phenotype Correlation

ALS is mainly a sporadic disease; familial cases are rare and occur only in about 10% of patients. Currently there are at least 10 genes that cause familial ALS, with *SOD1* being the most common followed by *FUS/TLS* and *TDP43*. The rest of the genes are very rare and sometimes restricted to certain ethnic backgrounds. A large number of ALS genes remain unknown.

A genetic etiology for the disease is readily suspected when there is a positive family history. Unfortunately, family history is not always available; it may be unknown to the patient if he is adopted or if one of the parents died at an early age before developing disease, if family history is not correctly collected, or if the information

obtained is restricted to the immediate patient's family. Incomplete penetrance may make familial ALS present like a sporadic disease.

In the absence of family history, certain clinical features may suggest a familial etiology, like an early age of onset, lower motor neuron presentation, the presence of atypical signs such as dementia, cerebellar features, or an unusually rapid or slow progression of symptoms.

Making the correct genetic diagnosis may help establish the diagnosis of ALS sooner and guide prognosis; however establishing an accurate phenotype–genotype correlation may not be easy, especially since some of the mutated genes harbor significant intra- and inter-familial variability.

These C9ORF72 expanded repeats are the most common genetic defect in ALS and ALS dementia. 50% of familial ALS patients, 5% of sporadic ALS patients and 61% of familial ALS patients with dementia carry the expanded allele of C9ORF72 (>23 repeats). For the most part, patients with *SOD1* mutations have a spinal onset of disease with predominance of lower motor neuron signs; cognition is usually spared with rare exceptions (189). Knowing the exact mutation can help predict disease duration. Disease progression is uniformly rapid in A4V and V148G patients, extremely variable with the I113T and slow with G37R, H46R and D90A. Scandinavian ancestry, slow progression and onset in the lower extremities suggest a D90A mutation.

The third most common gene implicated in familial ALS is *FUS/TLS*. Although most patient with the *FUS* mutation are indistinguishable from those with sporadic ALS, when compared to *SOD1* patients, *FUS* patients are found to have an earlier age of onset, a faster progression and a higher rate of bulbar disease (55). An atypical presentation with symmetrical proximal or axial weakness has been also reported by several groups for patients with *FUS* mutations (58,61,62). The presence of familial dementia should suggest *TDP43*, *FUS* mutation or familial FTD-ALS linked to 9p locus, whereas the presence of inclusion body myopathy or bone disease in the family should suggest *VCP* gene mutation. Optineurin and *SQSTM1* should be checked in a patient with ALS and Paget's disease of bone. Finally Angiogenin mutation should be checked in patients with Irish/Scottish background, while the *VAPB* gene should be evaluated in patients with Brazilian ancestors.

A very young age of onset or presence of disease predominantly in siblings should suggest a recessive inheritance. The predominance of upper motor neuron signs may point to an *ALSIN* gene mutation and the presence of mental retardation, dementia and atrophy of the corpus callosum and lower extremity spasticity may imply the presence of mutations in *SPATACSN* gene.

Finally the absence of male-to-male transmission should alert clinicians to the possibility of X-linked disease associated with ubiquilin2 mutation.

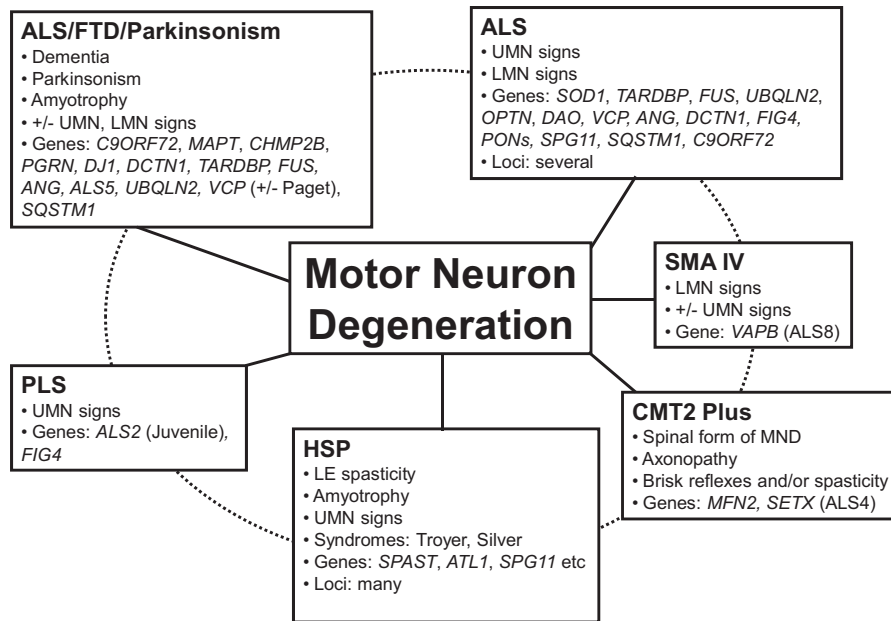

FIGURE 132-4 Phenome of ALS and related disorders.

## 132.9 CONCLUSION

ALS is a fatal disease of multiples etiologies; significant genetic progress has been made in the past decades with the discovery of several genes involved with familial ALS or related motor neuron degenerations (Figure 132-4). The discovery of these genes has allowed animal models of the disease to be engineered and helped in the understanding of pathogenic disease mechanisms and to test therapies.

ALS-associated genes have provided a unique opportunity to explore different pathways leading to motor neuron degeneration: from the role of oxidative stress, to protein aggregation, autophagy, abnormal RNA and DNA metabolism, and more recently defective protein and organelle degradation in the pathophysiology of ALS. In fact, recycling mechanisms may be at the heart of the molecular pathology not only of ALS, but also of several common neurodegenerative disorders.

The focus of genetic research has recently turned to sporadic ALS in order to discover susceptibility genes that will help identify specific environmental risk factors and to guide sporadic ALS modeling and therapy development for this incurable disease.

## Biographies

**Teepu Siddique** earned his MBBS from the University of Karachi and trained in neurology at UMDNJ-NJ Medical School, thereafter specializing in neuromuscular medicine. He completed fellowships at the Hospital for Special Surgery-Cornell Medical Center and the NIH. He held faculty appointments at the University of Southern California and Duke University before coming to Northwestern University, where he is the Les Turner ALS Foundation/Herbert C Wenske Chair and director of the Division of Neuromuscular Medicine.

Dr Siddique's research has focused on the molecular genetics of ALS and related disorders, employing a range of strategies to identify a number of genes that cause the inherited form (SOD1, ALSIN, FUS & UBQLN2), and genetic loci. His group has developed several animal models for neurodegenerative diseases, including SOD1- and ALSIN-ALS. Genetic factors associated with the risk of sporadic ALS have been uncovered. His recent work with UBQLN2 has demonstrated a defect in the protein degradation pathways as a common mechanism of sporadic ALS, familial ALS and ALS/dementia, paving the way for targeted treatments in ALS.

Dr Siddique has received national and international recognition, including the first Shelia Essey Award in ALS from the American Academy of Neurology, the Hope through Caring Award from the Les Turner ALS Foundation and the Forbes Norris Award.

**Dr Han-Xiang Deng** received his MD and a PhD in medical cytogenetics from the Central South University, Xiangya School of Medicine, China, and a PhD in human genetics and molecular biology from Nagasaki University School of Medicine, Japan. He then joined the faculty in the Department of Neurology, Northwestern University Feinberg School of Medicine. His research focus is the causes and pathogenic mechanisms of neurodegenerative disorders. He contributed to the identification of several genetic defects in neurodegenerative disorders, including SOD1, alsin and UBQLN2 for amyotrophic lateral sclerosis (ALS),  $\alpha$ -TTP for vitamin E deficiency, and TRPV4 for scapuloperoneal spinal muscular atrophy (SPSMA) and hereditary motor and sensory neuropathy type IIC (HMSN IIC, also known as HMSN2C or Charcot-Marie-Tooth disease type 2C (CMT2C)). He and his collaborators have developed and characterized several mouse models of neurodegenerative diseases for further understanding the pathogenic mechanisms.

**Dr Senda Ajroud-Driss** received her medical degree from The Medical School of Tunis, Tunisia; she completed her Neurology Residency at the University of Illinois at Chicago and her Neuromuscular Fellowship at Northwestern University Feinberg School of Medicine. Prior to her residency, she worked as a post-doctoral fellow in Dr Teepu Siddique's Neurogenetic laboratory at Northwestern University, establishing linkage of an autosomal dominant mitochondrial myopathy and later identifying its gene (not yet published).

She is Board Certified in Neurology and in Neuromuscular Medicine. She is currently an Assistant Professor in the department of Neurology at Northwestern University. She is involved in research and the clinical care of patient with familial and sporadic ALS.

## Color Vision Defects

*Samir S Deeb and Arno G Motulsky*

Division of Medical Genetics, Departments of Medicine and Genome Sciences, School of Medicine, University of Washington, Seattle, WA, USA

### 133.1 INTRODUCTION

The human retina contains two classes of photoreceptors, rods and cones. Rods are responsible for vision in dim light, whereas cones mediate vision in bright light and enable the perception of color. Individuals with normal color vision have three types of cone photoreceptors; the short wave-sensitive or blue, middle wave-sensitive or green, and long wave-sensitive or red cones. Such individuals have normal trichromatic color vision. Red/green color vision defects are common among males. Individuals with severe color vision defects usually either have non-functional red (protanopes) or green (deutanopes) cone photoreceptors. Such individuals have dichromatic rather than trichromatic color vision. Those with milder color vision defects usually have either their red or green cone photoreceptor pigments replaced by an anomalous pigment with altered spectral sensitivity. Such individuals are classified as having protanomalous or deuteranomalous trichromatic color vision (Table 133-1).

A wide variation in the ability to discriminate between colors exists among individuals with defective color vision. Subtle variation in color perception also exists among individuals with normal color vision. Significant advances have been made during the last 20 years toward understanding the molecular and genetic bases of variation in both defective and normal color vision. In this chapter, genotype to phenotype relationships in normal color vision and in the various classes of defective color vision will be reviewed. Rare color vision defects include tritanopia (loss of function of the blue opsin), blue-cone monochromacy or incomplete achromatopsia (loss of function of both the red and green opsins), and complete achromatopsia (loss of function of all three cone types). Emphasis in this chapter will be placed on the common red/green color vision defects. Genetics plays a central role in red/green color vision defects. The common defects result from unequal homologous recombinations between the highly homologous and adjacent red and green opsin genes on the X-chromosome.

**TABLE 133-1** Classification of the Common X-linked Recessive Color Vision Defects

Class	Retinal Cones			Frequency (European Men)	Color Discrimination
Normal					
Protanopia			No	~1%	
Protanomaly				~1%	
Deutanopia		No		~1%	
Deuteranomaly				~5%	

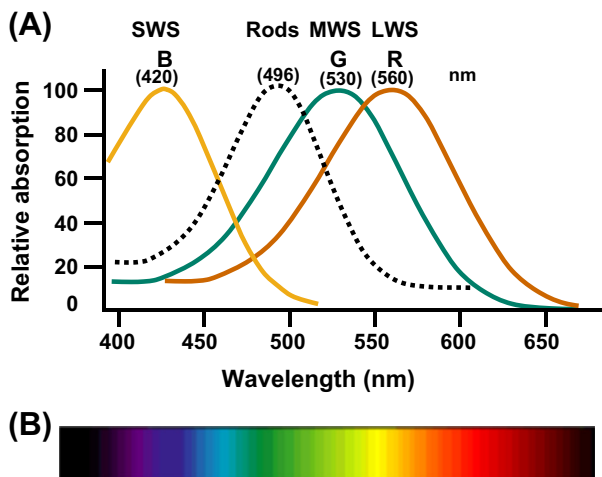

R', Red-like; G', Green-like types of cones. Color detection patterns in the visible spectrum are shown for normal trichromats and dichromats with protanopia or deutanopia. Anomalous trichromats (protanomalous and deuteranomalous) have a wide range of color discrimination capacity.

## 133.2 PHOTORECEPTORS

Each cone photoreceptor in the retina randomly expresses a single type of photopigment, which is fundamental to color perception. The wavelengths of maximal absorption ( $\lambda_{\max}$ ) of the photopigments of the blue, green, and red photoreceptors are at 420 nm, 530 nm, and 560 nm, respectively (Figure 133-1). The overlap between the absorption spectra of the three cone pigments allows color perception, by its ability to discriminate on the basis of wavelength. The sensation of various colors by the brain is based on comparisons of photon absorptions by the different cones.

The red and green cones are concentrated in the fovea, which is about 0.3 mm in diameter and contains about 10,000 cones. The fovea has no rods and very few blue cones, and has evolved as a specialized organ of high acuity and of red–green color vision. There are, on average, twice as many red cones as green cones in the fovea, with considerable variation among individuals. When the entire retina is considered, the average red/green pigment mRNA ratio is around 4.0, with a range of 1–10 (1). Variation in the red/green cone ratio makes little difference to color discrimination capacity. Color vision defects arise only at extreme ratios. The number of blue cones is 10%–20% of the total number of red and green cones. High-resolution imaging of the living human retina was accomplished using adaptive optics, and showed in two subjects that red and green cones are randomly arranged in the retina (2).

The pigment molecules are embedded within the membranes of the transverse disks of the outer segments of photoreceptors (Figure 133-2). There are about 1000 to 2000 transverse disks in a single photoreceptor, each containing about 100 pigment molecules.

**FIGURE 133-1** (A) Absorption spectra of human rod (dotted) and blue (B, SWS), green (G, MWS) and red (R, LWS) cone photoreceptors. The wavelengths of maximal absorption ( $\lambda_{\max}$ ) in nanometers (nm) are indicated. (B) Colors of the visible spectrum that can be detected by trichromats with normal color vision by comparison of signals generated by the different cones.

## 133.3 MOLECULAR BIOLOGY OF THE PHOTOPIGMENTS

A characteristic structural motif of the family of photopigments is the hypothetical trans-membrane bundle (see Figure 133-2), within which the chromophore retinal, a derivative of vitamin A, is held. The visual pigments belong to an evolutionarily-related superfamily of trans-membrane G-protein-coupled receptors that include the adrenergic, serotonergic, dopaminergic, and muscarinic and olfactory receptors. The evolution of vertebrate photopigments and color vision has recently been reviewed (3). It has been proposed that color vision in primates evolved as an adaptation to feeding on colored fruits and leaves, and that the absorption spectra of the cones were tuned by the reflectance spectra of these objects (4).

The four human photopigments share varying degrees of sequence homology. The red and green photopigments are more closely related to each other (96% amino acid sequence identity) than to any other visual pigments (40%–45% identity) because their ancestral gene duplicated recently during evolution. The  $\lambda_{\max}$  values for the red and green photopigments differ by approximately 30 nm (see Figure 133-1). Most of this difference is accounted for by differences at three amino acid positions of the red and green pigment proteins: Ala 180 Ser (4 nm), Phe 277 Tyr (10 nm), and Ala 285 Thr (16 nm), with amino acids to the left (see Figure 133-2) being in the green pigment and those to the right being in the red pigment. Minor spectral contributions are made by

**FIGURE 133-2** Diagram of a photopigment molecule embedded within the cone photoreceptor outer segment membrane. The cylinders represent the 7 $\alpha$  helices that form a bundle that holds the chromophore 11-cis retinal (represented by a magenta pentagon). The N- and C-termini of the pigment protein (opsin) are indicated. The difference in spectral sensitivity between the red and green pigments depends to a large extent upon amino acid residues at positions 180, 277, and 285. The above amino acid residues are positioned to interact with the chromophore. Amino acids to the left of residue numbers interact with the chromophore giving it the  $\lambda_{\max}$  of the red pigment those to the right interact with the chromophore giving it the  $\lambda_{\max}$  of the green pigment. The Ser at position 180 in the red pigment is commonly polymorphic (Ser/Ala), and the Ala at 180 in the green pigment is less commonly polymorphic (Ala/Ser). The change from Ser to Ala at position 180 of the red pigment decreases the  $\lambda_{\max}$  by approximately 5 nm.

differences at Ile 65 Thr, Thr 230 Ile, Ser 233 Ala and Phe 309 Tyr.

### 133.4 PHOTOTRANSDUCTION

The sensation of color results from a comparison of the signal outputs from the three types of cone photoreceptors, and is referred to as trichromatic color vision. The overlap between the spectral sensitivity curves of these photoreceptors (see [Figure 133-1](#)) allows this comparison at each wavelength of visible light. Light of a certain wavelength has a characteristic ratio of probabilities for exciting the blue, green and red photoreceptors. Individuals with normal color vision are able to perceive approximately 2 million colors.

The absorption of a single photon of light causes the isomerization of the retinal chromophore of the photopigments from the 11-*cis* to an all-trans configuration. This isomerization results in the formation of an activated intermediate of the photopigment that triggers the signal amplification cascade. The first step in this cascade involves activation of hundreds of transducin which in turn activate about 70 cyclic GMP phosphodiesterase molecules. The resultant decrease in cGMP levels triggers closure of cGMP-gated channel blocking sodium and calcium influx. This in turn leads to hyperpolarization of the photoreceptor cell membrane and creation of electrical signals that are transmitted to the brain and

**FIGURE 133-3** A brief diagram of the phototransduction cascade. This pathway converts a photon to an electrical signal in the retina that is transmitted to the brain. This pathway involves major amplification of the energy from a single photon. An absorbed photon activates the photopigment that subsequently activates about 100 molecules of the regulatory protein transducin. Each activated transducin molecule, in turn, activates the enzyme phosphodiesterase. Phosphodiesterase then catalyzes the hydrolysis of about 1000 cGMP (cyclic guanosine monophosphate) molecules to GMP (guanosine monophosphate). Since cGMP keeps the  $\text{Na}^+$  ion channels in the photoreceptor membrane open, reducing its intracellular concentration closes the channels. As a result,  $\text{Na}^+$  ions can no longer enter the cell, thus hyperpolarizing the photoreceptor membrane (the inside of the membrane becomes more negative). The electrical signals due to this hyperpolarization are transmitted to the brain, resulting in light and color perception. \*Points to three proteins (phosphodiesterase and the alpha and beta subunits of the cGMP-gated channel) in which mutations have been shown to cause achromatopsia.

allow sensation of color ([Figure 133-3](#)). See phototransduction videos at: <http://wn.com/phototransduction> for an illustration of this process.

### 133.5 GENES ENCODING THE PHOTOPIGMENTS

The cloning and characterization of the genes that encode the blue, red, and green photopigment apoproteins (opsins) have been largely due to the pioneering work of J. Nathans and his collaborators. The gene encoding the blue pigment (*OPN1SW*) is located on the long arm of chromosome 7. The genes encoding the green (*OPN1MW*) and red (*OPN1LW*) opsins are arranged in a head-to-tail tandem array ([Figure 133-4](#)) on the long arm of the X-chromosome (Xq28). The array contains repeat units (~40kb in length) starting with a red pigment gene, followed by one or more green pigment genes. The location of the three amino acids that contribute the major difference in the spectral properties of the red and green pigment genes are in exons 3 and 5 (see [Figure 133-4](#)). The two genes are almost identical in structure except for a 1.3kb insertion in intron 1 of the red pigment gene. This insertion was shown to be polymorphic among African Americans, 35%–45% of whom do not have this insertion. The red and green pigment gene repeats are 98% identical at the DNA sequence level. The intergenic regions (about 25kb in length) are also highly homologous in sequence. The high degree of homology between these repeat units predisposes the locus to relatively frequent unequal recombination and gene conversion contributing to the high frequency of color vision defects.

A master switch for expression of the red and green pigment genes, called the locus control region (LCR),

**FIGURE 133-4** Structure of the red and green pigment gene array on the X chromosome. Rectangles represent exons 1–6, and connecting solid lines represent introns. The red and green pigment genes are 15 and 13 kb respectively in length and are separated by approximately 25 kb of intergenic DNA. LCR, locus control region. The location of the three amino acid residues that contribute the majority of the 30 nm difference between wavelengths of maximal absorption ( $\lambda_{\text{max}}$ ) between the red and green pigments are indicated. Note the common Ser180Ala polymorphism in exon 3 of the red pigment gene. The number of green pigment genes in the array varies and is polymorphic. However, only the first two genes are expressed in the retina and, therefore, contribute to the color vision phenotype.

**FIGURE 133-5** Change in green pigment gene number due to unequal crossing over in women who have two X-chromosomes during meiosis. The red and green pigment gene arrays on the two X-chromosomes that are associated with normal color vision align out of register during metaphase of meiosis in females. A homologous unequal crossover occurring in the intergenic region produces gametes with altered numbers of green pigment genes. The lower position of the Figure shows the results of the crossover; a chromosome with three green genes and a chromosome with one green gene. Rectangles represent exons (1–6) of the red and green pigment genes, and connecting solid lines represent introns.

is located between 3.1 and 3.7kb 5' of the transcription initiation site of the red pigment gene. This control region is critical for ensuring mutually exclusive expression of the red and green pigment genes in individual cones, which is fundamental to color vision. It is thought that the LCR couples permanently in a photoreceptor progenitor cell with either the red pigment gene promoter and expresses the red pigment to form a red cone, or couples to the green pigment gene promoter to form a green cone.

It is believed that duplication of an ancestral red pigment gene occurred shortly after separation of the Old and New World primate lineages about 30–40 million years ago. This is in agreement with the observation that humans and Old World monkeys possess both red and green photopigment genes, whereas the majority of New World monkeys have a blue pigment gene on chromosome 7 plus a single red or green pigment gene on the X-chromosome. Interestingly, a New World monkey (*Alouatta*, the howler monkey) was found to have full trichromatic color vision due to the presence of both red and green photopigment genes on the X-chromosome due to a gene duplication that occurred independently in this species. Common polymorphisms in the single X-chromosome cone opsin genes were observed in the New World monkeys that are associated with the expression of either red or green pigments. Female heterozygotes for red and green encoding alleles were shown to have trichromatic color vision (3). Random X-chromosome inactivation during development of the retinas in such heterozygous females results in the formation of both red and green cone photoreceptors.

In individuals with normal color vision, the red pigment gene is located 5' of one or more green pigment genes (see Figure 133-4). The average number of green pigment genes in an array was shown to be 2 (with a

range of 1–6) in a population of European origin. The numerical polymorphism in the green pigment gene is due to unequal intergenic recombination (Figure 133-5). The number of green pigment genes in the array does not appear to influence either the number of green cones in the retina or the color vision phenotype since, as discussed later, only two genes (red and proximal green) of the array are expressed in the retina.

## 133.6 COLOR VISION TESTS

Many types of tests of color vision have been designed, some are simple and rapid for use in mass screening or in the clinical setting, and others are highly sophisticated and accurate for use in the laboratory setting. Four main categories of tests are briefly described: the plate tests, the arrangement tests, lantern tests, anomaloscopy and electroretinography (5).

For online testing see <http://www.TestingColorVision.com>

### 133.6.1 Pseudoisochromatic Plate Tests

The plate tests are designed in accordance with the color confusion characteristics of individuals with the various types of deficiencies. The plates contain designs in the form of numerals in various shades of color such that they are not seen (vanishing design) against the background by a color defective observer. In a second type of design (transformation), two figures are embedded in the background; one can be read by the color-defective observer and the other by the normal observer or vice versa. In the third design (the hidden design), the object can be seen by the color defective observer but not by the normal observer.

**133.6.1.1 The Ishihara Plates.** The Ishihara test (38 plates in the original version but also available as a standard test with 24 plates) is the most universally used test to screen for inherited red–green color vision defects. It is the most efficient plate test because it incorporates the vanishing, transformation, and the hidden designs as well as qualitatively diagnostic plates that allow differentiation of protan from deutan observers, and of the more severely affected dichromats from mild (but not from severe) anomalous trichromats. Inherited blue–yellow as well as acquired color vision defects (most of which are of the blue–yellow type) are not detected by the Ishihara test. Nevertheless, the Ishihara test is the most popular and reliable screening test that is widely available.

**133.6.1.2 The American Optical Company Hardy, Rand, and Ritter (AO HRR) Plates.** This test is used to screen for blue–yellow or tritan color vision defects but is less efficient in distinguishing normal from red–green color vision deficient subjects. Therefore, a combination of the AO HRR and the Ishihara tests would give the best complete assessment of color vision status that one could achieve using the plate method.

### 133.6.2 Screening Children for Color Vision Defects

The Ishihara and AO HRR plates can be used to screen for color vision defects in children from the age of seven years and older. Younger children are more difficult to screen but a specially devised eight-plate Ishihara test for unlettered persons based on shapes and tracing pathways has been successfully used on children as young as four years old.

### 133.6.3 Arrangement Tests

The arrangement tests involve asking observers to order a set of movable colored subjects according to either hue or saturation. This type of test assesses the color discrimination ability of both normal and color-defective individuals. The Farnsworth-Munsell 100-hue test (FM 100-hue test) consists of 85 color samples that span the entire natural color circle and are arranged in four boxes (21 or 22 colors each). In this test, the score for placement of each color sample is obtained by recording the absolute differences between the number designated for each sample (written on its reverse) and those of the adjacent samples. The scores are usually plotted to form a radial graph.

### 145.6.4 Lantern Tests

The US armed services (with the possible exception of the US Air Force), Coast Guard and Federal Aviation Agency medical examiners, use the “Farnsworth Lantern” (FALANT) as a color-naming test that simulates the identification of signal lights. This test is not used for clinical purposes. Nine pairs of colors (including red, green and white) are shown for initial assessment and are repeated twice if mistakes in naming of colors are made. The Pass/Fail level is based on the number of color naming errors. All dichromats and 75% of anomalous trichromats fail this test (2,9). There is no clear bimodality between passing and failing grades. Anomaloscopy or Farnsworth arrangement tests may identify anomalous trichromats who are likely to pass this lantern test.

### 133.6.5 Anomaloscopy

Anomaloscopy has been used widely for the detailed study and diagnosis of different types of color vision deficiencies. It is based on matching the color of a test light by mixing two other lights. Lord Rayleigh devised a simple test system to classify individuals with red-green color vision abnormalities. The observer views a pure yellow light (589–590 nm) on one half of a screen, whereas the other half of the screen projects a mixture of red (650 nm) and green (545–550 nm) lights. The brightness or intensity of the yellow light, as well as the proportion of the green and red lights, are adjusted by the subject until both hemi fields appear matched in color and brightness. Under the color conditions of

**FIGURE 133-6** Anomaloscopic Rayleigh match ranges of protan, deutan, and normal subjects. Horizontal bars represent the range of red and green light mixtures that each subject could match the standard yellow light. Numbers to the left of bars are for subject identification. P, Protanopia; PA, protanomaly; D, deuteranopia; DA, deuteranomaly; N, normal. (Data from Ref. 32).

the Rayleigh match, color detection by the short-wave sensitive or blue pigment cones is negligible. The most frequently used instrument is the Nagel Anomaloscope. The range of accepted matches of mixtures of green and red light against yellow is recorded, as is the mid-point of such matches. Figure 133-6 shows typical Rayleigh matches for normal and various color defective persons.

Normal observers accept a much narrower range of mixtures of red and green lights than color-defective individuals. Some color-defective individuals have both a wide match range and a shifted match midpoint, whereas others have only a shifted match midpoint. Dichromats such as protanopic and deuteranopic subjects will match yellow with any and all ratios of red and green, including red and green alone. Dichromatic deuteranopes require much more yellow to match pure red color than dichromatic protanopes, who need only a small amount of yellow to match the red field, which they perceive as of low intensity. Protanomalous subjects produce match ranges that are shifted to the red side of the spectrum, while the matches of deuteranomalous subjects are displaced to the green. Subjects with severe deuteranomaly and severe protanomaly tend to have relatively wide match ranges, while those with milder anomalous defects have narrower match ranges.

Definite diagnosis of protanopia, protanomaly, deuteranopia, and deuteranomaly requires anomaloscopy. This test is generally less available since anomaloscopy is not required for most clinical purposes in ophthalmology and optometry.

### 133.6.6 Electroretinography

In contrast to the various psychophysical methods of color vision assessment that rely on the observer's subjective perception of color, electroretinography (ERG)

is an objective means of determining the color vision phenotype. In ERG, a corneal electrode placed on an anesthetized dilated eye records the retinal response to standardized flashes of light. Because of the somewhat invasive nature of the test, extensive studies of the various inherited color vision defect have not been reported. However, color vision defects characterized as deutan and protan could be discriminated by the log ratio of the sensitivity at short (480 nm) and long (620 nm) wavelengths (sensitivity quotient). The use of ERG for detection of female carriers of protan and deutan defects was particularly successful for deutan carriers and less so for protan heterozygotes.

### 133.7 THE MOLECULAR BASIS OF VARIATION IN NORMAL COLOR VISION

Subtle variation in color perception in the red–green region of the spectrum has been observed among individuals considered to have normal color vision. Rayleigh color matches determined by anomaloscopy in male subjects with normal color vision fell into two main groups. Women with normal color vision formed a third and larger group with intermediate values of Rayleigh match midpoints. A similar independently described Rayleigh match variability fitted transmission by X-linked inheritance in families. These observations pointed to the presence of two common spectrally different forms of the red pigment gene.

Eight relatively common amino acid polymorphisms were discovered in the red pigment gene and five in the green pigment gene. The substitutions at three (Ser180Ala, Ile230Thr, and Ala233Ser) of these sites involved a change from hydroxyl-bearing to non-polar amino acid residues and, therefore, are likely to alter the spectral characteristics of the red pigment. The Ser-180Ala polymorphism was of great interest because it was quite common in the red pigment, occurring at a frequency of 64% Ser and 36% Ala in the studied population of European origin (serine occurred at a frequency of 16% in the green pigment).

We investigated the possibility that the common Ser180Ala polymorphism could underlie the above-mentioned phenotypic distributions of color vision. Fifty white men with normal color vision were tested for the hypothesis that the two major groups in the distribution of color matching could be explained by the Ser/Ala polymorphism in the red pigment. The frequency distributions of Rayleigh match midpoints and of the deduced amino acid sequence of the red photopigment show that higher sensitivity to red light (i.e. requirement of less red in the mixture of red and green lights to match the standard yellow light) was highly correlated with the presence of Ser at position 180 (Figure 133-7). Therefore, these men have a different perception of red light to those having the Ala allele at this site. The retinas of females who are heterozygous for the Ala and Ser alleles would be expected to contain an additional cone type that is red-like. This is

**FIGURE 133-7** Frequency distribution of Rayleigh match midpoints as a function of the presence of serine (Ser) or alanine (Ala) at position 180 in the red pigment. Individual male subjects with Ser or Ala at position 180 are represented by red and green rectangles, respectively. Rayleigh match ranges were determined by asking individuals to combine various quantities of red and color lights to match a standard yellow light (see Figure 133-6). Individuals with Ser at position 180 required less red light in the mixture of red and green lights to match the standard yellow light than did those who had alanine (Ala). (Data from Ref. 33).

due to the random X-chromosome inactivation during retinal development that results in expression of either the Ser red in some cones or the Ala red in others. Thus the retinas of such heterozygous females will have four cone types: blue, green, red and red-like cones.

### 133.8 THE MOLECULAR BASIS OF COLOR VISION DEFECTS

#### 133.8.1 Color Vision Defects

The inherited types of color vision deficiencies have been classified into three major categories: The red–green (protan and deutan) deficiencies, the blue–yellow (tritan) deficiencies, and the achromatopsias. The most common defects are by far the X-chromosome-linked red–green defects, which occur at frequencies of about 8% in men and 0.4% in women of European extraction. The blue–yellow defects and achromatopsias are rare. The frequency, mode of inheritance and symptoms are given in Tables 133-1 and 133-2.

#### 133.8.2 Red–Green Color Vision Defects

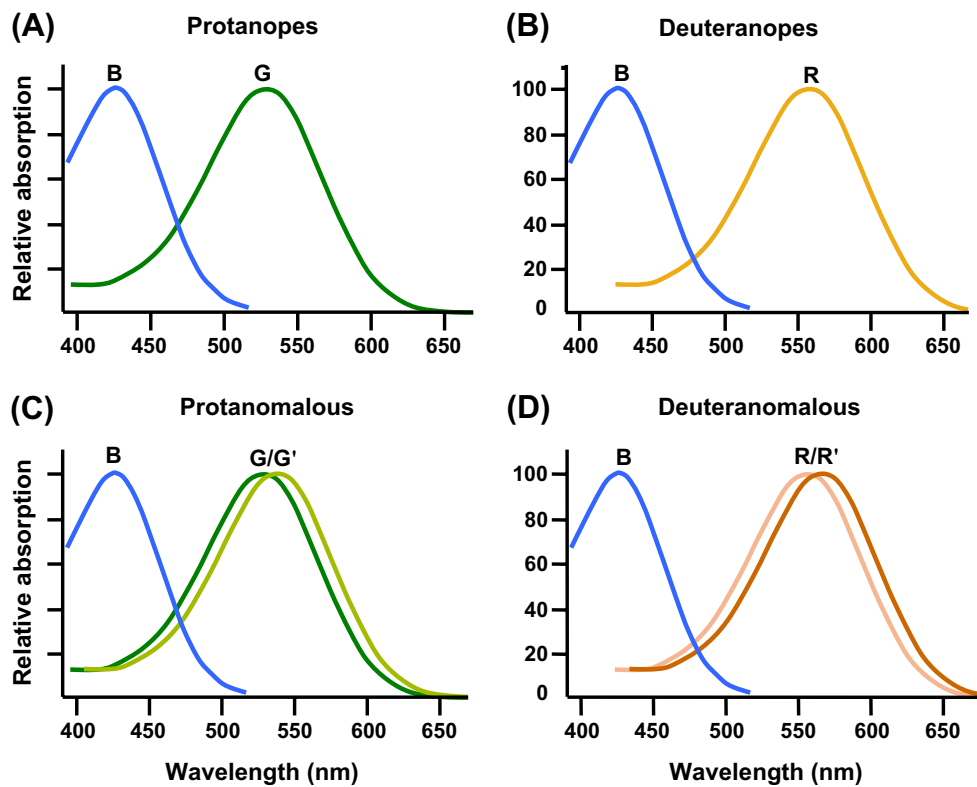

There is significant variation in the red–green color vision frequencies among populations of different ethnic groups.

**133.8.2.1 Subclasses.** Individuals with normal color vision can match the color of a test light of any wavelength composition by mixing the right proportions of three primaries, such as red, green and blue, or by mixing two of the primaries and adding the third to the test light. Therefore, they are referred to as having trichromatic

**TABLE 133-2 Classification of Rare Genetic Color Vision Defects**

Class	Retinal Cones			Frequency (European)	Color Discrimination
Normal					
Tritanopia (Aut dom)	No			~ 1/500	
Blue cone monochromacy (X-linked rec)		No	No	~1/100,1000	
Achromatopsia (Aut rec)	No	No	No	Very rare	

X-linked rec, X-linked recessive inheritance; aut dom, Autosomal dominant; aut Rec, Autosomal recessive. Color vision discrimination capacity includes simulated rainbow. B, Blue cone; G, Green cone; R, Red cone. The loss of B cones prevents discrimination of colors in the yellow, green and violet regions of the spectrum. Loss of R and G cones results in complete loss of color discrimination.

**FIGURE 133-8** Absorption spectra of cones of males with defective red-green color vision. The retina of a protanope has only blue (B) and green (G) cones (A), that of a deuteranope has blue and red cones (B) and both subjects have severe color vision defects. Protanomalous males have blue, green (G) and green-like (G') cones (C); deuteranomalous males have blue, red and red-like (R') cones (D) and both have milder color vision defects. The separation between the absorption spectra of normal and anomalous cone pigments is roughly inversely related to the severity of the color vision defect.

color vision. Individuals with severe color vision defects have lost one or more of the photopigments. In those with milder color vision defects, one of their normal pigments has been replaced by an anomalous pigment with altered spectral properties (Figure 133-8). Individuals who lack functional red or green cones are known as protanopes (P) or deuteranopes (D), respectively. They are able to match the color of a test light by mixing two primaries only

and therefore have dichromatic color vision. Individuals with only blue functional cones are classified as having monochromatic vision. A milder form of defective color vision among humans is anomalous trichromacy. Although anomalous trichromats appear to have three classes of photoreceptors, one of these classes has an anomalous spectral sensitivity. Protanomalous (PA) men have normal blue and green cones plus an anomalous red

cone with spectral sensitivity that is shifted significantly toward that of the green cone. Deuteranomalous (DA) individuals have normal blue and red cones, together with an anomalous green cone with a spectral sensitivity that is shifted toward that of the red cone.

### 133.8.3 Color Perception in Color Vision Deficiency

Color discrimination is a major component of our perceptual world. A large fraction (~8% of men and 0.5% of women) of the population of European origin has defective color vision and therefore perceives their environment differently. The frequency of the various color defects is less common in other continental populations (African males ~3% and East Asian males 3%–4%). Dichromats as a group have more abnormal color vision than anomalous trichromats. However, dichromats are said to have an advantage in penetrating military and natural scene camouflage. Dichromats were experimentally shown to be more proficient than observers with normal red–green color vision in detecting texture boundaries of target objects that are camouflaged by color.

A significant percentage (~15%–30%) of deuteranomalous trichromats (who constitute about two thirds of all color defectives) are not aware of their color vision defects. The most severely affected persons are protanopic

dichromats, followed by deuteranopic dichromats. Among the less severely affected trichromats, protanomalous men are more inconvenienced than deuteranomalous men. Protanopes and deuteranopes have problems discriminating red, yellow, and green but also deep red and deep brown. Colors of the red family may be perceived as black by protanopes. Most but not all dichromats have difficulty in discrimination and selection of colored articles, materials, and foods. Approximate simulations of how a natural scene appears to individuals with normal, protanopic, deuteranopic and tritanopic color vision are shown in Figure 133-9. The Web site (<http://jfly.nibb.ac.jp/html/colorblind>) describes various colors that color defective individuals have difficulty with, and includes instructions on how to prepare color presentations that are not confusing to color-deficient observers.

Recognition of red traffic light signals, barricade signal lights, and car or bicycle reflectors may be impaired, and reaction times may be slightly delayed among dichromats, particularly among protanopes. Poor lighting conditions may worsen color perception. However, color vision is not usually tested to obtain non-commercial driver licenses.

Having X-linked color vision defects has been used for many years to exclude applicants from a variety of employment, particularly among marine, air, rail, industrial and military occupations that require an ability to distinguish colors. Recent years have seen increasing use

**Normal**

**Protanope**

**Deuteranope**

**Tritanope**

**FIGURE 133-9** Simulation of the actual color vision of normals, protanopes, deuteranopes and tritanopes. Shown is a natural scene as it appears to a person with normal color vision and a simulation of how it appears to a protanope, deuteranope or a tritanope. Note that protanopes and deuteranopes are unable to distinguish red from green. Simulation was performed by the vischeck computer program that simulates human color vision and is freely available online at <http://vischeck.com/>.

of color-testing for a variety of practical applications that require color discrimination. Plate testing, such as the Ishihara test and the American Optical HRR plates, is usually employed for screening, and abnormal results may lead to rejection of job candidates. The use of a lantern test (such as FALANT [see earlier]) designed for practical testing by color naming may pass individuals such as those with deuteranomaly who fail plate-screening tests.

There are many occupations of all sorts including chemists, pharmacists, certain medical specialists, color printers, cartographers, commercial drivers and many others, in which color vision defects may be a handicap and may have significant consequences (6). In recent years, discrimination because of disability is increasingly condemned, particularly if such a “disability” has genetic causes; however, such “discrimination” may be justifiable if the color-defective person places others at risk or if he or she cannot adequately perform the required duties of employment. Therefore, rejection of color vision defectives for entry into certain occupations cannot be considered genetic discrimination, because the reason for not being hired has nothing to do with genetics per se but is based on job, public safety, or related issues. Decision making may not be entirely clear because, as an example, persons who are designated correctly as deuteranomalous by a plate test may be fully capable of carrying out practical tasks of color discrimination in certain jobs and may pass the lantern color test.

The relatively high frequency of color vision defects and the availability of reliable tests should lead to its wider detection among young people. Advice to avoid occupations that will cause problems for those with color vision abnormalities may be helpful and appropriate. At the same time, society and educational institutions should be aware of the extent of color vision defects and avoid colors on slides and computer screens that could be easily confused.

**133.8.3.1 Molecular Basis.** The molecular basis of the X-linked red–green color vision defects was first delineated by Jeremy Nathans and colleagues. They suggested that the various red–green color vision defects result from unequal homologous crossover or recombination between the red and green pigment gene units, leading either to deletions of the green pigment genes and/or to the formation of various types of full length red–green hybrid genes (Figure 133-10). The juxtaposition of the highly homologous red and green pigment genes during meiosis in females predisposed this locus to a relatively high frequency of such unequal recombination events. Subsequently, several studies have extended the delineation of the molecular bases of red–green color vision defects in various ethnic groups. The major findings of these investigations were:

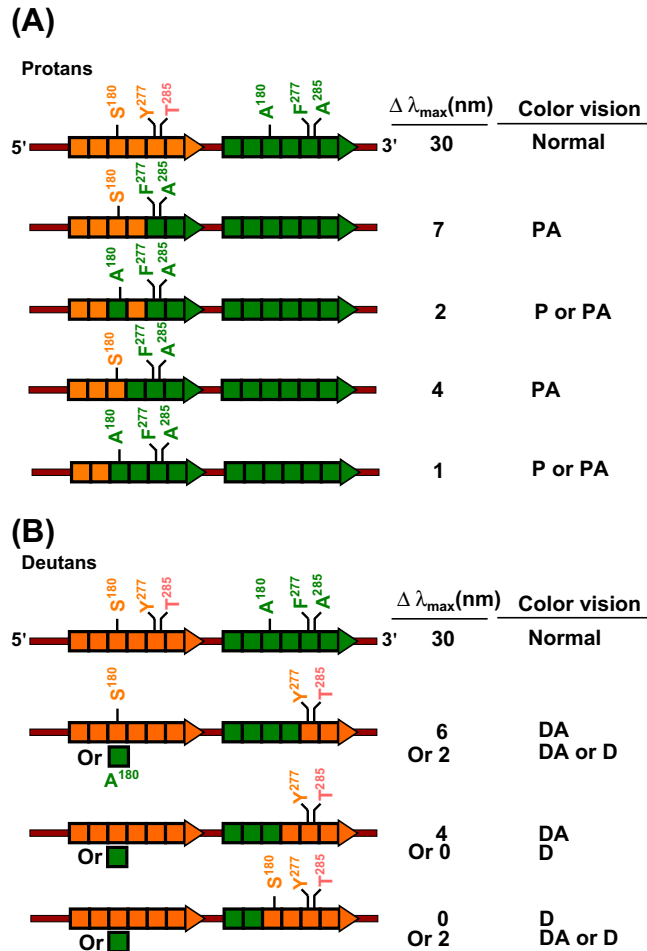

1. The majority of the *protan* red–green color vision defects are caused by conversion of the red pigment

gene to a variety of 5′ red–green 3′ hybrid genes that encode green-like pigments. The majority of *deutan* color vision defects are due to deletion of the green pigment gene or the conversion of the expressed green pigment gene to a variety of 3′ green–red 5′ hybrid genes that encode red-like pigments. In dichromats, *protanopia* is associated with gene arrays composed of a 5′ red–green 3′ hybrid gene found singly or together with normal green pigment genes, and *deuteranopia* was usually associated with gene arrays comprised of a single red pigment gene, and rarely with a red pigment gene together with a 5′ green–red 3′ hybrid gene. In anomalous trichromats, *protanomaly* was associated with gene arrays composed of a 5′ red–green 3′ hybrid and a normal green pigment gene, whereas *deuteranomaly* was associated with gene arrays composed of a normal red pigment gene, a 5′ green–red 3′ hybrid gene, in the absence or presence of a normal green pigment gene (Figure 133-11).

2. Exon 5 of the red and green color vision genes was found to play a major role in determining spectral sensitivity of the encoded photopigments. For example, replacement of exon five of the red pigment

**FIGURE 133-10** Unequal homologous crossing over in females during metaphase of meiosis leads to either gene deletion or the formation of red–green pigment hybrid genes. (A) Unequal homologous crossover in the intergenic region of the misaligned arrays of pigment genes leads to deletion of the green pigment gene(s), producing a single normal red pigment gene associated with deuteranopic (D) color vision deficiency, plus an array with one red and two normal green pigment genes. (B) Intragenic unequal crossover leads to the formation of 5′ red–green 3′ and the reciprocal 5′ green–red 3′ hybrid genes that are associated with either D or deuteranomalous (DA), and protanopic (P) Color vision defects, respectively.

**FIGURE 133-11** Genotype–phenotype relationships in men with protan and deutan color vision defects. Shown are examples of common gene arrays found among men with protan (Figure 133-11A) and deutan (Figure 133-11B) color vision defects. Rectangles represent exons (1–6) of the red and green pigment genes, and connecting solid lines represent introns. Amino acid differences at positions 180, 277 and 285 influence the major differences in  $\lambda_{\max}$  between the red and green pigments (A, alanine; S, serine; F, phenylalanine; T, threonine; Y, tyrosine). Differences ( $\Delta$ ) in  $\lambda_{\max}$  between the pigments encoded by the two genes in each array in males are indicated. The larger the  $\Delta \lambda_{\max}$  between the two pigments is generally associated with milder color vision deficiency. At low  $\Delta \lambda_{\max}$  (2 nm) the severity of the color vision defect is influenced by other factors, such as the density of the pigment in the photoreceptor. The hybrid genes were assigned the proximal position on the basis that distal hybrid genes are not expressed and therefore are not expected to cause color vision defects. Red–green and green–red hybrid genes are associated with protanopia (protanopic (P) or protanomalous (PA)) and deuteranopia (deuteranomic (D) or deuteranomalous (DA)). Color vision defects, respectively. Single gene arrays are associated with severe color vision defects (P) and (D) color vision defects. Multigene arrays are usually associated with milder defects unless the first two genes of the array encode pigment with identical or very similar (separated by 1–2 nm). The Ser180Ala polymorphism influences the  $\Delta \lambda_{\max}$  between the two pigments encoded by genes in the array and, therefore, the severity of color vision defects.

gene with that of the green pigment gene by unequal homologous recombination produced a hybrid pigment that was sufficiently green-like in its spectral

properties to make the subjects perform as *protans*. This result is consistent with the conclusions that differences at amino acid residues 277 and 285, which are encoded by exon 5, contribute the majority of the difference (24 of 30 nm) in wavelength of maximum sensitivity between the red and green pigments (see Figure 133-4).

3. Certain *deutan* men carried both green–red hybrid genes, as well as normal green genes. In theory, if all the genes were expressed in photoreceptors, these individuals would be expected to have normal color vision. In fact, about 6% of males with normal color vision carry such arrays. To explain this, we hypothesized that only the first two genes in the array are expressed in the retinal cone photoreceptors, as evidenced by analysis of red and green pigment mRNAs and by ERG on deutan subjects. Furthermore, in male eye donors who carry arrays typical of living *deutans* (normal red, normal green and a green–red hybrid gene), the green–red hybrid but not the normal green gene is expressed (7).
5. Based on studies of males with *deutan* and normal color vision, we determined, using long-range DNA amplification, that deutan color vision results only if the green–red hybrid gene occupies the second position in the array (Figure 133-12). We proposed that lack of expression of the green pigment genes that occupy third and more distal positions with respect to the locus control region (LCR) could be due to the very low probability of the LCR coupling to these genes and switching on their expression.
6. Point mutations were also found to cause relatively rare color vision deficiencies (8). For example, 2%–5% of *deutans* have a substitution of arginine for the highly conserved serine at position 203. The same mutation was also discovered as the cause of inactivation of a single red–green hybrid gene in about one third of probands with blue-cone monochromacy (see below). An association of an A→T substitution at position –71 of the promoter of the green pigment gene, located in the second position of the array, was found to be associated with *deutan* color vision in Japanese men (9). This is consistent with the observation that only the proximal green pigment gene of the array is expressed. The A-71T substitution has not yet been found among Europeans.

### 133.8.4 Relationship between Genotype and Severity of Color Vision Defects

The severity of color vision defects varies widely. A number of studies have addressed the question of how accurately the genotype at the red–green gene locus predicts the severity of the color vision defects. Because the presence of red–green hybrid genes is a common cause of color vision defects, these studies focused on determining

**FIGURE 133-12** Model for selective expression in the X-linked red/green pigment gene complex, and the importance of gene order in expression. Shown is a gene complex composed of a red, green and a 5' green–red 3' hybrid gene that can be associated with either normal or defective color vision (deutan) depending on the position of the hybrid gene. Note that only the first two genes in the array are expressed in the retina and, therefore, contribute to the color vision phenotype. (A) In the male carrying this gene complex, the locus control region (LCR) of the array turns on expression by activating the promoter (P) of the red pigment gene to form red cones, or the P of the proximal green pigment gene to form green cones. The green–red hybrid gene is not expressed because, most likely, it is much farther downstream from the activating LCR. Therefore, a male individual with this gene complex is expected to have normal color vision. (B) If the green–red hybrid gene occupies the second position in the array, the LCR expresses either the red or the green–red hybrid gene in a single cone photoreceptor. The normal green pigment gene, being located in the third position of this array, is not expressed. This gene arrangement would therefore be expected to be associated with deutan color vision defect in males because of the lack of normal green photoreceptors.

the structure of the gene arrays as well as the coding sequences of normal and hybrid genes they carry. Knowing the coding sequences of the genes allows inference of the spectral properties of the encoded pigments. For this purpose, we and others have developed a rapid polymerase chain reaction-based methodology to determine the sequence and number of genes in the red–green pigment array, as well as the presence, sequence, and in many cases, the position of hybrid genes in the array (10).

Theoretically, one would expect that men who carry a single-pigment gene or whose first two genes encode pigments with identical spectral properties to have the most severe color vision defects (dichromatic). This is what was generally observed (see Figure 133-11). There were a few exceptions, in that some of these men were severe anomalous trichromats instead of dichromats. These exceptions contradict fundamental color vision theory, because these subjects should have only blue and either red or green cones, yet they were able to make wavelength discriminations. Aside from differences in test performance, factors other than sequence of the pigments appear to influence the width of the Rayleigh match. These include variation in the ratio of red to green cones in the retina and in pigment optical density (quantity) (11) in photoreceptors.

Men whose first two genes of the array encode normal and anomalous pigments that differ in  $\lambda_{\max}$  would in general have milder color vision defects. The severity of such defects would be positively correlated to the  $\lambda_{\max}$  difference between the two pigments. Observations of both protan and deutan subjects roughly support this hypothesis (see Figure 133-11). The observed exceptions are those whose normal and anomalous pigments differ by 1–2 nm in  $\lambda_{\max}$  and are associated with either dichromatic or severe anomalous trichromatic color vision.

Again, other factors such as pigment optical density or retinal cone ratio, or both, may significantly influence the severity of the color vision defect when the difference between the two encoded pigments is small.

## 133.9 THE GENETICS OF RED–GREEN COLOR VISION IN WOMEN

### 133.9.1 Simple Heterozygotes

About two-thirds of female heterozygotes for red–green color vision defects are carriers of deuteranomaly, because this anomaly is the most frequent defect among men (5% of European male population). Random X-chromosome inactivation during early development allows expression of either allele of the red and green pigment genes on either chromosome in single cone cells. Psychophysical evidence is consistent with this prediction. The majority of protan and deutan heterozygotes have normal color vision by standard tests. Some heterozygotes have been found to have mild color vision deficiencies. In study of 31 obligate female carriers of color vision deficiency, Jordan and Mollon found that such subjects made significantly more errors on the Ishihara plates and had enlarged match ranges on Nagel anomaloscopy. The presence in the retinas of heterozygous women of four instead of three types of cone: blue, red, green and a fourth red–green hybrid, presents the potential for tetrachromacy. Tetrachromats possess four independent channels for processing signals from light resulting in a highly enhanced color discrimination capacity compared to trichromacy. We have recently tested this hypothesis in heterozygous carriers of protanomaly and deuteranomaly. The results showed that only one out of 24 carriers of deuteranomaly had

tetrachromatic color vision (12). A tetrachromat woman can see four distinct ranges of color instead of the three that trichromats can see. Three important factors seem to be important for having tetrachromatic color vision in female heterozygotes. One is a wide spectral difference between the normal and the additional anomalous pigment, the second is the relative ratio of cone types in the retina that vary considerably between individuals and is associated with color discrimination capacity, and the third is the role of optical density (the number of photopigment molecules per cone cell) in color discrimination. It may be possible that amino acid polymorphisms could alter the optical density of opsin molecules without changing their wavelength of sensitivity (13).

Rarely, a heterozygote may exhibit color vision deficiency, presumably as a result of extremely skewed X-chromosome inactivation of the normal allele, and thus express the defective allele. Skewed X-inactivation seems to be more common in one member of identical female twins. The frequency of this phenomenon among such heterozygote identical twin pairs is no more than 5%.

Molecular techniques usually cannot be used for the diagnosis of heterozygotes because such women carry both the normal and abnormal color vision gene arrays on their two X-chromosomes. However, heterozygotes for protan color vision defects can be identified because the red–green hybrid gene associated with such defects always occupies the first position in the array, and can be detected even in the presence of normal red pigment gene.

### 133.9.2 Compound Heterozygotes

Compound heterozygotes for red–green color vision defects have also been observed. Heterozygotes who carry an allele for deuteranomaly (presence of green–red hybrid gene) and an allele for deuteranopia (deletion of green pigment gene) on each of the two X chromosomes of different parental origin manifest with the milder phenotype of deuteranomaly. This is expected because their retinas have some cones with normal red pigment and others with the hybrid pigment. Similarly, protanomaly/protanopia compound heterozygotes manifest the milder phenotype of protanomaly.

In contrast, compound heterozygotes for protan and deutan defects on either the maternal or paternal X chromosomes have normal color vision, because some women have both normal red and green pigment genes and, therefore, are functionally heterozygotes for both protan and deutan defects.

### 133.9.3 Potential Gene Therapy in Red–green Color Vision Deficiencies

Improvement of color vision in dichromatic subjects (protanopic and deuteranopic) with severe color vision deficiency, being common among males, would be an important future accomplishment. The potential for

this improvement was tested in the dichromatic squirrel monkey that naturally has blue and green photoreceptors (14). Subretinal injection of a recombinant adeno-associated virus expressing the red pigment under the control of red pigment promoter and LCR was performed. The introduction of a third, randomly positioned, red cone photoreceptor into the retina resulted in trichromatic color vision behavior in this monkey. This provides the potential for similar gene therapy to improve color vision in humans in the foreseeable future.

## 133.10 BLUE–YELLOW (TRITAN) COLOR VISION DEFECTS

Inherited tritan color vision defects are much rarer than red–green defects and are characterized by selective loss of blue-sensitive photoreceptor function, causing greatly diminished or absent color discrimination in the blue–green region of the spectrum (450–480 nm). As in red–green defects, visual acuity is unimpaired. A survey in the Netherlands indicates that the frequency of tritan defects in the population may be as high as 1 in 500. The mode of inheritance is autosomal dominant, exhibiting variable severity of manifestation among affected members of a family.

Nine unrelated subjects with tritanopia have been reported. Heterozygosity for one of the following missense mutations in the gene encoding the blue pigment opsin, located on chromosome 7, has been shown to cause tritanopia: Gly79Arg in two Japanese subjects, Ser214Pro, and Pro264Ser and Arg283Gln. The retina of a subject with the Arg283Gln mutation was examined by adaptive optics technology. It was found that this mutation caused progressive blue cone dystrophy, as well as disruption of the regularity of the cone mosaic (15). The mutant alleles co-segregated with tritanopia in an autosomal dominant fashion; however, incomplete penetrance was observed in association with the Gly79Arg and Ser214Pro substitutions. The mutant gene(s) in two other known subjects with tritanopia remain unknown.

The dominant mode of inheritance suggests that accumulation of a defective opsin within photoreceptors causes either loss of function or cell death, reminiscent of the mutations in the rhodopsin and peripherin genes that cause a subset of autosomal dominant retinitis pigmentosa. Tritanopia has also been observed in association with some disorders of vision such as autosomal dominant juvenile optic atrophy.

## 133.11 THE ACHROMATOPSIAS

Achromatopsia refers to the complete absence of color discrimination capacity. Achromats can match any color to any other color by adjustment of the relative brightness. There are several types of inherited achromatopsia that fall into two major categories: typical complete and atypical incomplete (Table 133-2).

### 133.11.1 Typical Complete Achromatopsia: Total Color Blindness/Rod Monochromacy

Typical complete achromatopsia is inherited as an autosomal recessive trait with an incidence of approximately 1 in 30,000. In addition to loss of color discrimination, subjects suffer from reduced visual acuity from infancy, photophobia, and nystagmus. These symptoms reflect lack of function of all three classes of cone photoreceptors and vision is based on only rods. Adaptive optics technology was recently used to examine the status of cones in the living retina of a patient with achromatopsia. It was found that the size and density of cones in the fovea and parafovea were severely altered (16).

Phenotypic and genetic heterogeneities characterize this disorder have been reviewed (17). The first locus for this disorder was mapped to chromosome 2q11. The responsible gene at this locus is that encoding the  $\alpha$ -subunit of the cone photoreceptor cGMP-gated channel (*CNGA3*), located in the membrane of cone outer segment. This is a component of the signal transduction pathway in all three classes of cone photoreceptors (Figure 133-3). Mutations in this gene account for approximately 25% of all achromatopsia patients. *CNGA3* mutations were also observed among individuals with incomplete achromatopsia and in a few cases of cone dystrophy. The phenotypic heterogeneity is probably due to the extent to which the signal transduction cascade is affected by the mutation.

A second genetic locus for this disorder has been identified on chromosome 8q21–22 among patients from

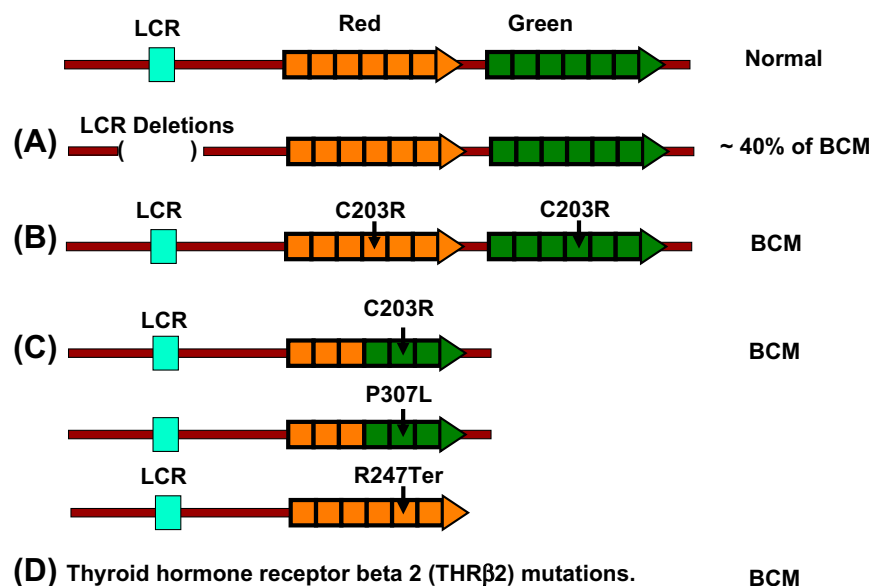

the Micronesian island of Pingelap and from European families. The incidence of achromatopsia on the island of Pingelap is about 10%, attributed to a founder effect. A description of the island of Pingelap and its inhabitants has appeared in the book *The Island of the Colorblind*. The responsible gene (*CGNB3*) encodes the  $\beta$ -subunit of the cone photoreceptor cGMP-gated channel (18). Mutations in this gene account for 40%–50% of all achromatopsia cases (19). It was demonstrated in the mouse retina that the proteins encoded by the *CNGA3* and *CGNB3* form the channel by heterotetrachromatic complex interactions (20).

Mutations in a third gene, a cone photoreceptor guanine nucleotide  $\alpha$ -subunit of the cone transducin gene (*GNAT2*) on chromosome 1p13, was shown to account for about 2% of these cases (21). The  $\alpha$ -subunit of the cone transducin is a key component of the signal transduction pathway in all classes of cone (Figure 133-2).

An achromatopsia network has recently been established: (<http://www.achromat.org/>).

### 133.11.2 Gene Therapy of Achromatopsia

The genetic causes of achromatopsia result in loss of function but not death of cone photoreceptors, providing an ideal model to re-establish functionality by gene therapy. This has been positively accomplished in knockout mouse models of the *GNAT2* (22) or the *CNGA3* (23) genes using sub-retinal injection of recombinant adeno-associated virus (AAV) gene therapy. A successful, stable restoration of cone function and day vision was also

**FIGURE 133-13** Four genetic mechanisms of causing blue-cone monochromatism (BCM). (A) Deletion of the locus control region (demarcated by brackets) that prevents expression of both red and green pigment genes. (B) Point mutations (C203R) that inactivate both the red and green photopigments. The C203R is the most common point mutation associated with BCM. (C) Gene deletion due to unequal recombination leaving the first gene in the array, followed by point mutations in the coding sequences (C203R, P307L or R247-to-Ter) with deleterious effects on the encoded photopigment. All three mutations cause BCM. (D) Homozygosity for mutations in the thyroid hormone receptor beta 2 gene (THRβ2).

accomplished in a canine model with achromatopsia due to a mutation in the *CNGB3* gene (24). The recombinant AAV used contained the promoter of the red pigment gene as well as the locus control region. The success and stability of cone function was higher in young-treated models (25), perhaps due to progressive loss of cones.

### 133.11.3 Atypical Incomplete Achromatopsia: Blue Cone Monochromacy

Blue cone monochromacy (BCM), also referred to as Pi1 monochromacy, or X-linked recessive incomplete achromatopsia, is an extremely rare disorder (less than 1 in 100,000) in which both red and green cone functions are absent. Therefore, using the remaining functional blue cones, the wavelength composition of light cannot be perceived since this requires comparisons between the outputs of signals from at least two cone types (see Table 133-2).

This disorder is characterized by severe reduction in visual acuity, central scotoma (corresponding to the blue cone-free fovea), infantile nystagmus and sometimes myopia. Progressive central retinal dystrophy has been reported in some patients with BCM, indicating that cone degeneration may result from the accumulation of an abnormally assembled photopigment in analogy with the mutations in rhodopsin found to underlie autosomal dominant retinitis pigmentosa. Bilateral macular atrophy has also been observed in a family with blue cone monochromacy due to a deletion of the locus control region.

There is a specific test that distinguishes between BCMs and rod monochromats. In this test, the subject is shown four plates, each containing three identical blue-green arrows and one purple-blue arrow. The plates differ from one another only in the chromaticity of the purple-blue arrow. Blue-cone monochromats can distinguish the purple-blue arrows in all four plates. Rod monochromats cannot.

Nathans and colleagues analyzed the structure of the red-green locus in individuals from 38 families with BCM. They found two mutational pathways that lead to this phenotype. One, found in 14 families, involved deletions (587–55 kb) that included a regulatory sequence located approximately 3.4 kb 5' upstream of the transcription initiation site of the red opsin gene (Figure 133-12). In some of these individuals, the red and green opsin genes were intact, whereas in others the deletions extended into the red opsin gene. This deleted regulatory region, referred to as a locus control region (LCR) (see earlier) was shown, in transgenic mice, to be essential for directing expression of both long and short wavelength-sensitive cones in the mouse retina.

The second pathway leading to BCM, found in 20 families, involved unequal homologous recombination between the green and red opsin genes that reduced the

gene array to only a single red or a 5' red-green hybrid gene (Figure 133-13). In 16 of these families, the green opsin portion of the hybrid gene had a Cys203Arg substitution, which rendered the encoded hybrid opsin nonfunctional (26). Interestingly, the same Cys203Arg mutation was found to be relatively common (2%) in the green opsin genes of white men (27b).

### 133.11.4 The Role of Thyroid Hormone in Color Vision

There is good evidence that thyroid hormone, by activating thyroid hormone receptor  $\beta 2$  (THR $\beta 2$ ), is critical for expression of the red and green pigment genes (27), leading to differentiation of red and green cones during development. THR $\beta 2$  also suppresses blue cone formation during development. Thr $\beta 2$ -null mice (28) were shown to have only blue cones due to loss of ability to differentiate green cones. A thyroid-resistant human subject was shown to have blue cone monochromacy (Figure 133-13) (28).

A thyroid-resistant patient who is compound heterozygote for mutations in THR $\beta 2$  had severely reduced red and green cone function (28).

### 133.11.5 Enhanced Blue-Cone (or S-Cone) Syndrome

Enhanced blue-cone syndrome is autosomal recessive disorder of photoreceptor cell fate. It is characterized by hyper-differentiation of blue cones at the expense of rods, and blindness in the late stages. Mutations in the orphan nuclear receptor *NR2E3* gene were shown to cause this syndrome (29). *NR2E3* (also called PNR) plays a critical role in differentiating rods and suppressing the cone pathway (30).

## Biographies

**Dr Samir S Deeb** obtained his undergraduate degree in Agricultural Engineering in 1957 from the American University of Beirut, Lebanon. He then went to Colorado State University and graduated with a Master's degree in Nutrition in 1959. Subsequently, he spent four years at the University of Illinois, Champaign-Urbana, where he graduated with a PhD in Chemistry (major in Biochemistry) in 1964. Molecular genetics became of great interest to him, and he spent 2.5 years as a postdoctoral fellow with Dr Benjamin Hall in the Genetics Department at the University of Washington. From 1965–1983 he was a faculty member in the Biology Department at the American University of Beirut, Lebanon. He taught courses in cell biology, biochemistry, evolution, and genetics. His research focused on molecular genetics, particularly on the genetic basis of beta-thalassemia in Lebanese families. During this period, he was invited to the University of Illinois as a visiting faculty member in the Department of Biochemistry, spent one year on sabbatical and another year as a visiting faculty at the University of Colorado, Boulder. From 1976–1983 he was Chairman of the Biology Department, American University of Beirut. In 1983, he moved to the University of Washington, Seattle, where he is presently a Research Professor in the Division of Medical Genetics, Department of Medicine, and affiliate in the Department of Genome Sciences. His research at the University of Washington included the molecular genetic of dyslipidemias, coronary artery disease, type 2 diabetes, Alzheimer's disease, and color vision. In collaboration with Drs Arno Motulsky and David Teller (Department of Psychology), he contributed significantly to the molecule genetics of color vision. He has authored over 200 articles.

**Arno G Motulsky** is internationally recognized and honored for his achievements in research, training, and organization in the field of human genetics. He founded the Division of Medical Genetics at the University of Washington in 1957. This unit was among the first efforts that led to medical genetics becoming a key specialty of medicine. His research has spanned a wide variety of topics, including hematological genetics, clinical genetics, and pharmacogenetics. He is a founder of the field of pharmacogenetics. He initiated studies on the genetics of hyperlipidemia in coronary artery disease, which launched the spectacular career of Nobelist Goldstein. With Samir Deeb he contributed to the understanding of the molecular genetics of color vision and its defects. He has authored over 400 articles and several books, including the "Human Genetics" with Friedrich Vogel. The 4th edition with two additional editors and multiple co-authors appeared in 2010. He holds a variety of positions on editorial boards.

Dr Motulsky is an elected member of the National Academy of Sciences, the American Academy of Arts and Sciences, the American Philosophical Society, and the Institute of Medicine, as well as of the American Society of Clinical Investigation and the American Association of Physicians. Besides honorary doctorates, he has received several major prizes for his work in human and medical genetics.

This article is a revision of the previous edition article by Veronique J Arnould-Devuyst, Irene Hussels Maumenee, Bruce R Korf, volume 3, pp 3115–3132, © 2007, Elsevier Inc.

### GLOSSARY

**Dyschromatopsia** – difficulty or inability to discriminate colors, sometimes of a particular type (e.g. tritan deficiency is difficulty with discrimination along the blue–yellow axis).

**Ganglion cells** – the innermost neural retina cells whose axons form the optic nerve.

**Nystagmus** – an involuntary, rhythmic or wandering movement of the eyes that may be caused by early-onset visual dysfunction and/or brain pathology.

**Optic nerve** – the second cranial nerve, consisting of axons from ganglion cells of the retina and glial tissue. These axons largely synapse in the lateral geniculate nucleus of the thalamus, after partially decussating at the optic chiasm.

**Papillomacular bundle** – the mitochondria-rich ganglion cell axons which synapse with macular neural retinal.

**Scotoma** – a complete or relative inability to discriminate a light stimulus at a particular location of the visual field.

### 134.1 INTRODUCTION

The optic nerve is composed of over 1 million axons that originate in the retinal ganglion cells (the innermost cellular layer of the retina) and synapse largely in the lateral geniculate nucleus of the thalamus. These axons gather at the posterior portion of the eye, where—along with central nervous system glial tissue—they form the optic disc. It is largely from clinical examination of the optic disc that optic atrophy—a loss of retinal ganglion cell axons—is diagnosed. The optic nerve travels through the posterior orbit and through the optic canal of the skull. The two nerves meet at the anterior floor of the third ventricle to form the optic chiasm; there, the nasal fibers from each eye decussate to the opposite side of the brain, whereas the temporal fibers remain ipsilateral. In general, anything that causes harm to retinal ganglion cells or injures their axons along this course will lead to optic atrophy. Injury may be primary (e.g. the accumulation of metabolic products in some lysosomal storage diseases) or secondary (e.g. compression of the optic nerve by overgrowth of bone in the optic canal).

Hereditary optic atrophies may occur primarily as isolated disorders or as part of a systemic syndrome. Because some “primary optic nerve diseases” can sometimes include systemic features, this distinction is not always crisp. This chapter will focus on the two most common primary optic atrophies encountered in clinical genetics practice, namely, dominant optic atrophy (DOA, OMIM#165500, *OPA1*) and Leber hereditary optic neuropathy (LHON, OMIM#535000), although some attention will be given to rarer forms of optic atrophy. Although LHON and DOA differ in their clinical presentation and their genetics (Table 134-1), both result from abnormal mitochondrial function. Readers are referred to Chapter 11 for a discussion of basic mitochondrial physiology and genetics.

### 134.2 “PRIMARY” OPTIC ATROPHIES

#### 134.2.1 Dominant Optic Atrophy (Kjer Type) (MIM#165500, *OPA1*, \*605290)

Using Danish pedigrees, Kjer defined the clinical features of dominant optic atrophy (DOA), distinguishing it from Leber hereditary optic neuropathy (LHON) (1). Although he differentiated two dominant forms—one congenital with nystagmus and one infantile with no nystagmus—he questioned whether this division represented the phenotypic range for the same genetic condition. DOA is typically a bilateral, symmetric, primary optic atrophy, with an insidious onset in childhood. Progression is generally slow, resulting in variable visual acuity and field loss with a dyschromatopsia (classically, yellow-blue/tritan type) and optic nerve pallor (2). The prevalence of DOA is approximately 1:35,000 (English cohort) to 1:12,000 (Danish cohort), making it one of the most common forms of inherited optic atrophy (3).

**134.2.1.1 Clinical Features.** DOA typically has an insidious to subacute onset in the first decade of life. It has been described in children as early as age 2 years and is often detected when the child starts school; it can occasionally

**TABLE 134-1 Comparison of the Clinical Features of Dominant Optic Atrophy and Leber Hereditary Optic Atrophy**

	Leber Hereditary Optic Atrophy (LHON)	Dominant Optic Atrophy, Kjer Type
Inheritance	Mitochondrial DNA, maternal	Autosomal Dominant
Typical age of onset	2nd–3rd decade	1st–2nd decade
Presentation	Acute, painless visual loss	Chronic, painless, insidious visual loss
Gene(s)	<i>MTND4</i> (m.11778G>A) <i>MTND1</i> (m.3460G.A) <i>MTND6</i> (m.14484T>C) Collectively account for >90% cases	<i>OPA1</i> , 3q28–q29
End stage	Optic nerve pallor, legal blindness	Optic nerve pallor, legal blindness
Treatment	None	None

start later in life. A British study had, for example, two peaks of age of onset of the symptoms: 5 and 21–30 years (4). Similarly, Johnston et al. found that 58% of individuals had symptoms before the age of 10 (5). Since the identification of mutations in the nuclear-encoded *OPA1* gene in a significant percentage of patients with DOA (6) (see below), some clinical reports have focused on patients with confirmed mutations, whereas others have included both mutation-positive and mutation-negative patients. How (if at all) this affects the interpretation of these clinical data is still a subject of debate.

Bilateral loss of visual acuity is the main presenting symptom in DOA. The visual prognosis is relatively good: distance vision typically ranges from 20/70 to 20/100, but can be as good as 20/20 (subclinical), or as poor as light perception (although this is uncommon) (2,4). Visual acuity is usually symmetric, with a typical disparity between the impaired distance vision and the comparatively conserved near vision. DOA is typically slowly progressive, although this may not be universally true (3a,7). Given that DOA predominantly affects the papillomacular bundle (which serves central vision), visual field deficits are usually central or cecentral, with relative sparing of the retinal periphery. Although a tritan color deficit is classic for DOA, Votruba et al. found that over 80% of individuals have a mixed color deficit (4); color vision defects may precede loss of acuity. These same authors note that there is significant intra- and inter-familial variability in phenotype.

Pallor of the temporal optic nerve is the major finding on fundus examination (Figure 134-1). Eliott et al. found that there was no strict correlation between acuity and the degree of optic nerve pallor (8). Recently, Barboni and colleagues noted that the optic nerve heads of DOA patients are generally smaller than in age-matched controls (9). Retinal nerve fiber thickness, as measured with optical coherence tomography (OCT), is most severely affected in the temporal quadrant, with relative sparing of the nasal quadrant (10,11). The macular reflex may be unremarkable, decreased, or absent. In contrast to LHON, no vascular changes are described. Barboni et al. argue that the loss of nerve fiber layer thickness over time is similar to the normal aging process, although theirs was

a cross-sectional rather than a longitudinal study (11). The full field electroretinograms (ERG) is typically normal, but the pattern ERG shows a reduced N95 component, in agreement with primary ganglion cell dysfunction (4).

Approximately 20% of patients with *OPA1* mutations will develop a more severe disease variant, called “dominant optic atrophy plus” (DOA+), with additional neuromuscular features. In addition to cases featuring sensorineural deafness, ataxia, myopathy, peripheral neuropathy, and progressive external ophthalmoplegia (12), Yu-Wai-Man et al. uncovered two novel clinical presentations of DOA: spastic paraparesis was present in two families with DOA, while a phenotype similar to that of multiple sclerosis was exhibited in another family. Defective cytochrome C oxidative phosphorylation in skeletal muscle is a subclinical feature of patients with *OPA1*-related dominant optic atrophy, indicating a systemic expression of the *OPA1* defect (13). Retinal nerve fiber layer thinning is more pronounced in patients with DOA+ phenotypes (10). Yu-Wai-Man hypothesized that the involvement of other tissue types in DOA+ may be a direct consequence of the greater accumulation of secondary mitochondrial DNA abnormalities, the latter potentiating an already compromised mitochondrial oxidative reserve due to the mutant *OPA1* protein.

The differential diagnosis includes neuropathies and retinopathies with optic atrophy. LHON, recessive optic atrophy, toxic optic neuropathy, demyelinating diseases, hereditary macular dystrophies have to be considered (14).

Histopathologically, optic atrophy is characterized by general atrophy of the ganglion cell layer as well as partial atrophy of the optic nerve, without atrophy of the outer retinal layers. There is increased collagen in association with a decreased number of neurofibrils and myelin sheaths in the optic nerves, optic chiasm, and optic tracts (15).

**134.2.1.2 Genetics and Pathogenesis.** DOA is inherited in an autosomal dominant fashion (1); however, recent evidence has suggested that *OPA1* may actually result from semi-dominant inheritance (16). In 2000, two groups simultaneously reported on mutations in the *OPA1* gene in DOA (6). Although the penetrance of *OPA1* mutations approaches 100%, the expressivity of the phenotype is quite variable. Pathogenic *OPA1* mutations

**FIGURE 134-1** Dominant optic atrophy. (A) Right eye (OD). (B) Left eye (OS). This 37-year-old man has 20/30 vision in both eyes, a tritan color defect, and exhibits the characteristic temporal pallor and atrophy of the disc.

account for about 60% of all cases (17). The *OPA1* protein localizes to the mitochondria (1) and encodes a GTPase related to the dynamin family of proteins (6). In general, *OPA1* mutations are predicted to result in a loss of protein function, although dominant negative effects of missense mutation alleles have also been proposed. Several lines of evidence suggest that mutations in *OPA1* result in deficient mitochondrial function and bioenergetics. Skeletal muscle from patients with *OPA1* mutations showed reduced mitochondrial adenosine triphosphate production (13). Magnetic resonance spectroscopy similarly shows a reduced ATP peak in patients with *OPA1* mutations (18). Decreased mitochondrial DNA content is found in peripheral blood of some patients with *OPA1* mutations (19). Amati-Bonneau et al. show increased mitochondrial network fragmentation and decreased mitochondrial membrane potential in skin fibroblasts from patients with R445H mutations in *OPA1* (20). Elachouri et al. have recently presented evidence that *OPA1* is important in maintenance of the mitochondrial DNA,

as silencing of the *OPA1* gene in vitro resulted in mitochondrial DNA depletion due to deficient replication (21). In a *Drosophila* model, Yarosh et al. found that vitamin E and superoxide dismutase were able to reverse the dOpa1 phenotype, suggesting a role of reactive oxygen species in disease pathogenesis (22).

There is evidence of locus heterogeneity in DOA. *OPA1* is located on 3q28–29 (6,23). Kivlin et al. described a large North American family of German descent that showed a maximum lod score of 2 at a recombination fraction of 0.18 using the Kidd blood group antigen, which was later assigned to 18q12 mapped a locus (*OPA4*, OMIM #605293) (24). This locus was further refined by Kerrison et al. (25). Reynier and colleagues identified two different heterozygous mutations in the *OPA3* gene (see below) in two families with DOA and cataract (26). Barbet et al. have reported a three-generation French pedigree with DOA that maps to 22q12.1–q13.1 (*OPA5*, OMIM #610708) (27).

**134.2.1.3 Management.** No clinically proven treatment is available. Caution should be observed in translating findings from animal models into humans. Family screening, genetic counseling, and possible molecular diagnosis are indicated.

### 134.2.2 Leber Hereditary Optic Neuropathy (MIM 535000)

Leber hereditary optic atrophy (LHON) was first described by Theodor Leber in 1871 as a nosologically distinct optic neuropathy. It has long been postulated to be caused by a defect in mitochondrial metabolism, and the first mitochondrial DNA (mtDNA) mutation was found by Wallace's group in 1988 (see Chapter 11) (28).

LHON has to be distinguished from Leber congenital amaurosis, an autosomal recessive chorioretinal dystrophy that presents with poor vision at birth. This latter disorder can be associated with variable amounts of optic atrophy. Prevalence of LHON is estimated as 1 in 31,000 to 1 in 50,000, which is comparable to DOA.

**134.2.2.1 Clinical Features.** LHON is classically characterized by painless visual loss typically beginning in one eye, and eventually progressing to the other eye over an average interval of 2 months (29). Although rare unilateral cases have been reported (30), the rule is that the second eye will be affected within one year of initial presentation. Up to 25% of cases may present with bilateral visual loss. The deterioration of vision ranges from acute to subacute, and is followed by stability after 3–4 months. Most cases present in the second or third decade of life and approximately 90% of carriers who develop visual loss will do so by age 50 (31). Vision loss, however, can occur at any age and LHON should be included in the differential of acute sequential and/or bilateral optic neuropathy even in older and younger individuals. While approximately 20–60% of at-risk males experience visual loss, only 4–32% of at-risk

females develop visual loss (29). This incomplete penetrance and difference in gender susceptibility has been observed across multiple ethnic groups (32). The precise reason for these observations is unclear.

Careful electrophysiological and psychophysical testing has revealed abnormalities in color discrimination, subtle edema of the nerve fiber layer, subclinical central scotomas, abnormal multifocal ERGs, and abnormal visual evoked potentials prior to the onset of overt symptoms (33). Given the ethical and social consequences of presymptomatic diagnosis (e.g. inability to obtain disability or long-term care insurance), care should be taken in approaching the examination of asymptomatic family members of an affected individual.

Classically, the disease occurs as “thunder in a dry sky,” i.e. as an isolated vision loss without prodromal symptoms, although migraine-like headaches occur in up to 33% of the affected patients (34). During the acute phase, circum-papillary telangiectatic blood vessels, hyperemia of the disc, vascular tortuosity of the retinal blood vessels, and intracellular edema of the nerve fiber layer without leakage on fluorescein angiography are typical (Figure 134-2). Affected individuals develop a central or cecentral scotoma and impaired color vision. Pupillary responses may be relatively preserved for the degree of vision loss (35). However, some patients experience symptoms while presenting with of a normal eye exam, sometimes leading to an erroneous initial diagnosis of functional vision loss. Over time, the optic nerve becomes increasingly pale. The final visual outcome is variable, ranging from 20/50 to no light perception. Vision loss is generally permanent, although there may be some mild recovery of “islands” within the visual field over time. Kirkman et al. have documented significant effects of LHON on patients’ quality of life, as scored on the Visual Function Index (VF-14) questionnaire (36). Some genotype–phenotype correlation has been reported (see below).

With the advent of OCT, one can now correlate physical abnormalities of the retina and optic cup with the severity of visual acuity changes in patients with LHON. Spectral domain OCT allows for high resolution imaging and quantitative analyses of the retinal layers, thus allowing for sequential analysis of the progression of disease in LHON patients, as well as distinguishing between retinal disorders of the inner retinal layers and disorders of the outer retinal layers, such as LHON and DOA (37). The retinal nerve fiber layer (RNFL) is thickened in early (<6 months duration) LHON, and severely thinned in late (>6 months duration) LHON, with inferior and temporal fibers (papillomacular bundle) being the first and most severely affected (38). Additionally, males with LHON demonstrate a more diffuse retinal nerve fiber layer involvement than females on OCT imaging (33a). When assessed by Heidelberg Retina Tomograph (HRT), the eyes of LHON patients demonstrated significantly larger cup parameters, smaller rim volume, and thinner mean RNFL thickness than controls (39). Newman et al. found presymptomatic changes in static automated perimetry in patients with LHON (40).

Magnetic resonance imaging (MRI) of LHON patients typically demonstrates an acute enlargement of the anterior visual pathways without enhancement, as well as increased T2 signal from the optic nerves to the lateral geniculate bodies. Follow-up imaging a few months later often demonstrate persistent bright T2 signal in normal-sized or atrophied anterior visual pathways (41). LHON lesions may be distinguished from those of multiple sclerosis because they tend to be less than 5mm in diameter, lack sharp boundaries, and do not enhance with gadolinium (42).

Although limited reports of histopathology of the LHON optic nerve exist, Kerrison et al. noted optic atrophy and double-membrane bound inclusions consisting of calcium in retinal ganglion cells in tissue from a

**FIGURE 134-2** Leber optic neuropathy. (A) OD. (B) OS. This 23-year-old man presented with a three-month history of decrease in vision when first seen. His initial examination disclosed hyperemic discs typical of the acute optic neuritis stage of the disease. The vision dropped to its lowest a few weeks later (20/200 OD and CF at 4ft OS). (C) OS. (D) OS. Two years later, fundus examination reveals the subsequent typical total bilateral optic atrophy, while his vision had increased to 20/25 in both eyes. He was found to have the 11778 mutation.

symptomatic 81-year-old woman (43). Molecular analysis confirmed homoplasmy for her mitochondrial mutations in ocular tissue.

In most instances, LHON manifests as an isolated optic atrophy, but cardiac and neurologic manifestations may occur. Cardiac conduction abnormalities may become symptomatic and occasionally even life-threatening (44); they consist of pre-excitation syndromes, specifically Wolff–Parkinson–White and Lown–Ganong–Levine syndromes, or prolongation of the corrected QT interval, which has been observed in the female carriers. Because these conduction anomalies can be severe, an ECG should be obtained. The reported neurological abnormalities are uncommon and diverse in presentation (45). Nikoskelainen et al. performed neurological

exams on 38 men and 8 women with LHON and suggest a pathological relationship between LHON and various movement disorders, multiple sclerosis-like illness, and deformities of the vertebral column—a relationship dubbed “Leber’s plus” (46). The multiple sclerosis-like phenotype associated in some patients with LHON—particularly those with an m.11778 G>A mutation (see below)—is sometimes referred to as “Harding’s syndrome” (42,47). Vanopdenbosch et al. have suggested, in fact, that carrying a primary LHON-related mutation is a risk factor for developing MS (48). While no consensus exists on the utility of neuroimaging in patients with LHON, asking carefully about neurologic symptoms and/or documenting a systemic neurologic exam may be reasonable precautions.

**FIGURE 134-3** Mitochondrial DNA with primary and secondary point mutations responsible for Leber hereditary optic neuropathy. (Modified from Newman, N. J. *Leber’s Hereditary Optic Neuropathy: New Genetic Considerations*. Arch. Neurol. 1993, 50, 540–548, with permission.)

**FIGURE 134-4** Behr optic atrophy in a 24-year-old man with pallor of the optic nerve head and unexplained tremor since early childhood. A, OD. B, OS.

**134.2.2.2 Genetics and Molecular Mechanisms.** LHON is the prototypical disease caused by mutations in maternally-inherited mitochondrial DNA. As such, all children of a woman carrying an LHON mutation are expected to inherit the same mutation, whereas children of men with LHON are not at risk of inheriting the mutation. Despite this prediction, over half of patients present with no family history (49).

Between 90 and 95% of patients with LHON harbor one of three primary mutations in the mitochondrial DNA: m.3460G>A (in MTND1), m.11778G>A (in MTND4), or m.14484T>C (MTND6). All three mutations are in genes coding for subunits of Complex I in the electron transport chain. Numerous other rare mitochondrial DNA mutations have been reported, some of which have not been proven to be pathogenic (see Yu-Wai-Man et al. for a recent review) (14). The m.11778G>A mutation is the most prevalent change in most populations, although m.14484T>C accounts for nearly 90% of French Canadian cases of LHON.

Molecular analysis has suggested a correlation between specific mitochondrial mutations and visual recovery (31). The 14484 mutation has the best prognosis, with a recovery rate, defined as a VA of 20/60 or better in both eyes, of 37%. The 3460 mutation recovery rate is variable but may reach 22%. The 11778 mutation has the worst prognosis with recovery seen in only 5% of patients.

Why do only a subset of males and a minority of females carrying a bona fide LHON mutation develop overt disease; and when they develop disease, why is it usually isolated to the optic nerve? While the precise answers to these questions are unclear, both environmental and genetic (nuclear and mitochondrial) factors may play a role. The optic nerve—particularly the papillomacular bundle—is highly dependent on ATP production from mitochondria, perhaps making it particularly susceptible to metabolic insult. Many other tissues, however, also have a strong reliance on mitochondrial ATP production, so this answer is, at best, incomplete. Some mitochondrial DNA mutations are present in only a fraction of a cell's mitochondria (heteroplasmy). A cell must accumulate some threshold of abnormal mitochondria—usually thought to be 60–80%—before it develops problems in bioenergetics (50). The most common mitochondrial DNA mutations are most often, however, homoplasmic (at least in the tissues assayed). Hudson et al. found that the haplogroup on which a mitochondrial mutation occurs (see Chapter 11) may influence the clinical outcome (51). Specifically, individuals with m.11778G>A and m.14484T>C were more likely to have significant visual loss when on the J haplogroup, while m.3460G>A were more susceptible to disease on the H haplogroup.

One attractive hypothesis that would help explain the proclivity of male carriers for developing disease is that a locus on the X-chromosome modifies the LHON phenotype. Bu and Rotter studied more than 1200 individuals from 31 large pedigrees to create a two-locus model for visual deficits in LHON, with the X-locus acting in synergy with the primary mitochondrial DNA mutation (52). Several groups have performed mapping studies and identified candidate loci on the X-chromosome—some of which overlap (53). To date, the precise gene (or genes) responsible for this process have not been identified and some groups have failed to confirm significant disease modification by an X-linked locus.

Another possibility is that the LHON phenotype is influenced by hormonal factors. Evidence suggests that estrogens may metabolically ameliorate mitochondrial dysfunction in this disease process (54). Giordano et al. found that LHON cybrid cells treated with 17 $\beta$ -estradiol activated the antioxidant enzyme superoxide dismutase 2, additionally resulting in decreased apoptotic rate, decreased production of reactive oxygen species, and decreased the number of mitochondria with hyperfragmented morphology. Additionally, 17 $\beta$ -estradiol induces a general activation of mitochondrial biogenesis,

**FIGURE 134-5** Hereditary optic nerve hypoplasia. Both sibs present with bilateral small and pale optic discs. A, 18-year-old young man (right eye). B, Nine-year-old brother (left eye).

and increases in vitro cell viability. Estrogen receptor  $\beta$  was also verified to localize to the mitochondrial network of human retinal ganglion cells via immunofluorescence and Western blot analyses.

Another variable affecting disease expression may be environmental factors, particularly those known or thought to be toxic to mitochondrial function. Kirman et al. studied 196 affected and 206 unaffected carriers, from 125 LHON pedigrees known to harbor one of the three most common LHON mitochondrial DNA mutations (55). Using a structured questionnaire, they found a strong, dose-dependent association between tobacco use and vision loss, with a clinical penetrance of greater than 90% in men who smoked. Alcohol intake tended—at least in its extreme—to predispose to vision loss, but this did not reach statistical significance. Case reports have suggested that cyanide (a known inhibitor of the mitochondrial respiratory chain), cocaine, MDMA (ecstasy), telithromycin (56), erythromycin (57), anti-tuberculosis medications (58), nutritional deficiencies (59), occupational solvent exposure (60), borreliosis (61), anemia

(62) and trauma (especially recent head trauma) may also affect disease expression.

**134.2.2.3 Treatment.** To date, there is no proven treatment for LHON. The timing and variable disease course associated with this disease makes the evaluation of any treatment through objective studies extremely difficult. Deciding what clinical outcome variables are most relevant (e.g. acuity, visual field, OCT findings) is not trivial. In the case of localized treatments such as gene therapy, deciding when and whether to treat the affected eye or the unaffected eye is also an important consideration.

Newman et al. evaluated the effectiveness of brimonidine purite eye drops in a nonrandomized, open label prospective pilot trial of nine patients (63). The goal of this trial was to determine whether the reported neuroprotective effects of brimonidine would reduce the rate of second eye involvement, after presentation with vision loss in one eye. The trial was complicated by the finding that seven patients had subtle findings of second eye involvement at the time of presentation (40). Based on their results, the authors conclude that brimonidine used at the concentration tested was not effective in preventing second eye involvement.

The short-chain synthetic benzoquinone, idebenone, is a potent antioxidant and inhibitor of lipid peroxidation that interacts with the mitochondrial electron transport chain, allowing the “bypass” of complex I. Mashima et al. first described the remission of LHON in a 10-year-old boy with idebenone administration in 1992 (64). A subsequent, small, noncontrolled trial has suggested that oral administration of idebenone, when coupled with vitamins B12 and C supplementation, may speed up visual recovery in affected patients (65). Since then, a multi-center randomized placebo-controlled trial of 900 mg idebenone per day in 85 LHON patients demonstrated that idebenone was safe and well-tolerated, and suggests that patients with discordant visual acuities are the most likely to benefit from idebenone treatment (66). A retrospective study of early and prolonged idebenone treatment in patients with acute LHON has similarly demonstrated that idebenone administration may significantly improve the frequency of visual recovery and possibly change the natural history of the disease (67).

Because most data suggest that the pathogenesis of LHON is due to a loss of function in electron transport chain proteins, gene replacement is an attractive therapeutic strategy. So long as the protein is targeted by the cell to the mitochondrial inner membrane, nuclear or episomal gene replacement (allotopic expression) would be predicted to be effective (68). In vitro studies suggest that gene replacement in cells from LHON patients improves mitochondrial function (68b,69). Animal studies have suggested that expression of wild-type complex I subunits is safe. Lam et al. have recently reported on the clinical characteristics of LHON patients with the G11778A mutation in anticipation of a gene therapy trial (70).

**FIGURE 134-6** Optic nerve malformations. A and B, Optic nerve hypoplasia associated with deMorsier syndrome. C, Marked optic nerve hypoplasia. D, “Morning Glory anomaly” of the disc.

Because tobacco and alcohol may act as mitochondrial toxins, avoiding smoking and excess alcohol intake is a reasonable precaution in patients who present with LHON or who are known/suspected carriers of an LHON mutation (55).

### 134.2.3 X-Linked Optic Atrophy (MIM %311050, *OPA2*)

A rare, early-onset, slowly progressive form of optic atrophy limited to males and accompanied by developmental delay and neurologic symptoms has been recognized since the 1970s. Using some of these original pedigrees, Assink et al. performed multipoint linkage analysis, placing the locus for this condition on Xp11.–p11.21 (71). The developmental delay and neurological abnormalities reported in these earlier studies may not be a consistent part of the phenotype, as Katz et al. describe a US family with similar ophthalmologic features but no neurological abnormalities, which potentially maps to the same locus (72).

### 134.2.4 Costeff Optic Atrophy Syndrome/ Type III 3-Methylglutaconic Aciduria (MIM\*606580, *OPA3*)

Type III 3-methylglutaconic aciduria (MGA, MIM 258501)—which is synonymous with *OPA3*—is an

autosomal recessive disease characterized by increased urine excretion of 3-methylglutaconic acid and 3-methylglutaric acid, early-onset bilateral optic atrophy and subsequent neurological and cognitive deficits. Anikster et al. used linkage analysis in 40 Iraqi Jewish patients to localize the *OPA3* locus to 19q13.2–13.3 (73). They identified a cDNA clone, FLJ22187, corresponding to a two exon gene in which a point mutation co-segregating with the phenotype was observed. The transcript of this gene is widely expressed, including in the skeletal muscle, brain and kidney. The *OPA3* protein is localized to the mitochondria (74). It is unclear whether patients who have 3-methylglutaconic aciduria, but not the full-blown Costeff syndrome, may harbor mutations in the *OPA3* gene (75).

Reynier et al. found that a form of autosomal dominant optic atrophy with cataract (MIM 258501) is allelic to *OPA3* (26). These authors posit that the two missense mutations they identify in their cohort may lead to disease via a mechanism other than haploinsufficiency, as the carrier parents of patients with Costeff optic atrophy syndrome—who appear to be haploinsufficient—are asymptomatic. This hypothesis is somewhat at odds, however, with the observation in a murine model containing a missense mutation in *Opa3* (76), where heterozygous mice are asymptomatic, but homozygous mice mirror the Costeff syndrome phenotype. Yu-Wai-Man et al. did not observe any *OPA3*

mutations in their cohort of 188 patients with either autosomal dominant or sporadic optic atrophy (77).

### 134.2.5 OPA4 (MIM %605293)

*OPA4* is the designation of autosomal dominant optic atrophy mapping to 18q12.2–12.3 described by Kerrison et al. (25) and previously linked to the Kidd blood group. These patients have a range of visual acuities from normal to legal blindness.

### 134.2.6 OPA5 (MIM %610708)

Barbet et al. describe a dominant optic atrophy in two unrelated French families that showed linkage to 22q12.1–q13.1 (27). The visual acuity loss in these patients began between the first and third decade of life and slowly progressed.

### 134.2.7 Autosomal Recessive Congenital/Early Infantile Optic Atrophy (MIM %258500, OPA6)

Barbet et al. reported on a consanguineous French family where four living individuals were affected by an early-onset, but slowly progressive, optic neuropathy (78). A genome-wide scan for homozygous regions identified a potential disease locus at 8q21–22. The authors exclude coding sequence changes in the *CNGB3*, *DECR1*, and *PDP1* genes in this region.

### 134.2.8 Non-Syndromic Autosomal Recessive Optic Atrophy; Optic Atrophy 7 (OPA7, MIM #612989)

This form of autosomal recessive juvenile-onset optic atrophy is characterized by severe bilateral visual acuity loss, optic disc pallor, and central scotoma. Identified by Hanein et al. (2009) in a large multiplex Algerian family and 3 other Maghreb families, onset usually occurs between 4 and 6 years of age. All but one of the affected individuals demonstrated strictly normal peripheral visual fields.

Affected individuals may or may not demonstrate partial deficiency in mitochondrial complex activity. One affected individual demonstrated partial deficiency of complex I, hypertrophic cardiomyopathy, mild hearing loss, and minor brain MRI alterations, all of which suggest mitochondrial dysfunction.

This form of optic atrophy is caused by a homozygous mutation in the transmembrane protein 126A gene (*TMEM126A*, MIM 612988). This mitochondrial protein, found in higher eukaryotes, is located at 11q14.1. The gene product contains 4 transmembrane domains, as well as a central domain conserved with *TMEM126B* (79). In contrast to *OPA1* mutations, cells carrying *OPA7* mutations do not demonstrate mitochondrial fragmentation and/or depletion of mitochondrial DNA,

thus suggesting that *TMEM26A* and *OPA1* are not functionally related.

## 134.3 COMPLEX OPTIC ATROPHIES

### 134.3.1 Behr Syndrome (MIM %210000)

Recessive bilateral optic atrophy of early onset with variable, severe neurologic signs, especially pyramidal, was described by Behr in 1909. This clinical entity is probably a heterogeneous group of disorders, whose root causes are mostly unknown; as such, a true “Behr syndrome” as a distinct clinical and genetic entity may not exist (see discussion below). Some have disputed that the cause of vision loss in some cases may not have been related to optic atrophy per se, as a retinal dystrophy was not ruled out. Alternative names are Behr complicated form of optic atrophy and complicated infantile optic atrophy.

The disorder has its onset in childhood, between the ages of 1 and 9 years, and is typically stable after an initial and variable period of progression. It is characterized by bilateral optic atrophy, seen on fundus examination as mild pallor of the disc, more marked temporally and rarely complete. The visual acuity is usually poor and measures about 20/400. There will be moderate to severe dyschromatopsia. Nystagmus is present in half the cases, and strabismus coexists in two thirds. Visual field defects can be present as central scotomas or temporal ones, which are rarely complete. The ERG is unremarkable in those patients where testing has been performed.

The neurological abnormalities resemble Friedreich ataxia: increased tendon reflexes, presence of Babinsky’s sign, hypertonia, mild ataxia and spasticity, and mental retardation.

Autopsy of one affected child showed optic atrophy as well as atrophy of the optic tracts. There were extensive degenerative changes in the lateral geniculate nuclei (LGN); disruption of the normal lamination of the LGN was present with dropout of neurons and gliosis. Changes in other thalamic nuclei and in the pallida were evident, but there was no demonstrable lesion in the cortex to correlate with the associated mental retardation. Horoupian and collaborators (80) interpreted the findings as showing a primary degeneration of the LGN with retrograde degeneration leading to optic atrophy.

Recessive inheritance is suggested by the involvement of siblings, with equal frequency in children of both sexes and by an increased frequency of consanguinity among the unaffected parents; however, an autosomal dominant inheritance pattern has also been described (81). The gene has not been mapped.

A major complexity in classifying Behr syndrome as a separate clinical and genetic entity is that the phenotypic expression is quite similar to other forms of optic atrophy with neurological signs. For example, some patients classified as having a “Behr-like”

syndrome were subsequently found to have type III 3-methylglutaconic aciduria and mutations in *OPA3* (73,82). The degree to which Behr syndrome overlaps with type III 3-methylglutaconic aciduria is made even more uncertain by the fact that the abnormal urine profile may not be picked up by routine urine organic analysis (83). No other genetic cause of Behr syndrome has been identified to date, although case studies of *OPA1* mutations in Behr syndrome patients may suggest that classical Behr syndrome should be re-classified under the umbrella of dominant optic atrophy-plus phenotypes (84).

As with other inherited optic atrophies, there is no proven effective treatment and care is supportive.

### **134.3.2 Wolfram Syndrome (WFS1: OMIM 222300; WFS2: OMIM 604928; Mitochondrial: OMIM 598500)**

DIDMOAD is an acronym for diabetes insipidus, juvenile-onset diabetes mellitus, optic atrophy and sensorineural deafness. Also known as Wolfram syndrome, the phenotypic variability of this autosomal recessive condition has led to other acronyms (e.g. DMOA) that include some, but not all, of the “classic” findings. In addition, patients may present with neurological deterioration (ataxia, peripheral neuropathy, myoclonus, psychiatric disease), gut dysmotility, primary and secondary hypogonadism, anterior pituitary dysfunction and urological findings (hydronephrosis, hydroureter, dilation of the urinary bladder) (85). The presence of optic atrophy and juvenile-onset diabetes mellitus are considered mandatory for the diagnosis. Barrett et al. estimated the population frequency to be about 1 in 770,00, with a 1 in 354 carrier frequency (85a).

Juvenile-onset diabetes mellitus may be the first manifestation of the syndrome, appearing between 2 and 20 years of age, usually within the first decade. Unlike classic type 1 diabetes, patients with Wolfram syndrome do not develop antibodies against islet cells; HLA-associated risk predictions are also different (86). The French Wolfram Group, headed by Cano et al, compared 26 Wolfram syndrome patients to 52 type-1 diabetes mellitus patients matched for age of diabetes onset. This study demonstrated a lower daily insulin requirement and lower hemoglobin A1c levels in Wolfram Syndrome patients, despite their use of a less intensive insulin regimen (87). Additionally, the study by Cano et al. demonstrated decreased prevalence of diabetic retinopathy, nephropathy, and other microvascular complications in patients with Wolfram Syndrome compared to type 1 diabetics. Fifty patients with Wolfram syndrome-related diabetes (WSD) were compared with the data of 24,164 patients with type 1 diabetes, and this demonstrated that WSD was diagnosed earlier than type 1 diabetes, with a lower prevalence of ketoacidosis (88). Additionally, this study demonstrated a correlation between WFS1 mutations (see below) and

age of diabetes onset, and identified glucose toxicity as an accelerating factor in disease progression. C-peptide stimulation indicated a small remaining insulin secretory reserve. Additionally, compared to wild-type beta cells, WFS1 deficient cells demonstrate impaired granular acidification, which is normally required for the priming of secretory granules preceding exocytosis. This may suggest a molecular mechanism for the profound impairment of glucose-induced insulin secretion in WFS1-knockout mouse models (89). WFS1-deficient beta cells exhibit increases in markers indicative of endoplasmic reticulum (ER) stress, thus causing beta cell loss through impaired cell cycle progression and increased apoptosis (90).

Progressive visual loss due to primary optic atrophy usually follows the diabetes mellitus symptoms and starts between the ages of 2 and 24 years, most often before age 15 years, with an average age of onset of 11 years. Visual impairment is severe, resulting in acuities of 20/2000–20/6000 (0.01–0.003), but ranges from 20/200 to hand motion. There is progressive, marked, diffuse pallor of the optic disc, which may be absent at the time of first complaints of vision loss. In a study of fifteen Wolfram syndrome patients, the prevalence of optic atrophy was 93.3%, color loss was 92.9%, cataract was 66.6%, pigmentary retinopathy was 30%, and diabetic retinopathy was 20% (91). Visual field testing in some cases demonstrates concentric and/or peripheral vision loss (92). In the retina, electrooculograms and ERGs are usually normal in the presence of reduced cone/rod dark adaptation, although Dhalla et al. report a case with pigmentary retinopathy (93). Neuropathological specimens demonstrate loss of retinal ganglion cells, myelinated axons in the optic nerve, chiasm, and tract, as well as neuron loss in the lateral geniculate nucleus (94). Diabetic retinopathy is extremely rare; the overall course is milder than that seen in isolated diabetes mellitus, with a lower prevalence of microvascular disease (87).

Hearing loss is present in about 66% of individuals with Wolfram syndrome, with the preferential involvement of high frequencies (95). Hearing impairment ranges from congenital deafness to a milder, progressive sensorineural hearing loss, and median age of onset is 12.5 years (85a). Among individuals with inactivating WFS1 mutations, five females demonstrated significantly greater hearing impairment than four males, thus suggesting a role for hormonal factors in hearing loss modulation (96). Neuropathological findings in Wolfram syndrome patients demonstrate loss of the organ of Corti in the basal turn of the cochlea, as well as focal atrophy of the stria vascularis, correlating well with high-frequency hearing loss (94).

Diabetes insipidus (DI), present in 51–87% of individuals (85b,97), is most often central in origin and usually presents in the second decade of life. Brain MRI may show absence of the typical T1-hyperintense signal from the posterior pituitary along with atrophy and gliosis in the supraoptic and paraventricular nuclei (PVN) of the hypothalamus (98). Necropsy has demonstrated similar

findings, as well as accumulation of vasopressin precursors in the PVN (99).

Neurological abnormalities, including neurodegeneration, are present in more than half of patients with Wolfram syndrome (85a). Widespread neurodegenerative changes, with a median age of onset of 15 years, are considered part of the syndrome and are supported by abnormal MRI findings, making Wolfram syndrome part of a multisystem neurodegenerative disorder. Progressive neurological findings are the result of generalized brain atrophy, with the involvement of cranial nerves, the brain stem, pons, cerebellum, and posterior hypothalamus (85a,98a,100). The most prominent atrophy was demonstrated in the cerebellum, medulla, pons, optic nerves, and posterior hypothalamus (101). Neuroimaging may also show atrophy of other brain regions in the setting of neurodegeneration, although this atrophy does not always result in patient symptoms (98a). Cognitive impairment, corresponding to cortical abnormalities on MRI, may also be observed in up to 32% of patients with neurological signs (102). DI and hearing loss have been correlated with degenerative damage of the hypothalamus and the vestibulocochlear nuclei (94). Ataxia has been correlated with Purkinje cell loss and gliosis in the cerebellar white matter (103). In a postmortem study, Hilson et al. demonstrate gross shrinkage and neuron loss in the pontine base and inferior olivary nucleus, as well as minimal neurohypophyseal tissue in the pituitary and decreased numbers of axons in the paraventricular and supraoptic nuclei, with relative sparing of the cerebellum (94).

Gastrointestinal complaints have also been noted in a large number of Wolfram syndrome patients, with 25% of patients complaining of constipation, chronic diarrhea, and other bowel dysfunctions. Some of these cases have been attributed to gluten intolerance, which is 20 times more frequent in patient populations who have had several years' history of diabetes mellitus (104).

Autosomal recessive inheritance with incomplete penetrance is supported by reports of families with more than one affected sibling, and consanguinity is noticed in 15%–32.5% of the cases. Many of the described cases are sporadic.

Wolfram syndrome is genetically heterogeneous and is currently subdivided into three genetic forms: WFS1 (MIM \*606201), WFS2 (MIM#604928), and a possible mitochondrial syndrome (MIM#598500). WFS1 is located on 4p16.1 and encodes a transmembrane ER glycoprotein called wolframin, which may function as a calcium channel or a regulator of calcium conductance in the ER (105). Khanin et al. found mutations in 90% of their patients with Wolfram syndrome (106). Wolframin is ubiquitously expressed, with particularly high levels in the pancreas, heart, brain and in insulinoma beta-cell lines (107). Disease likely results from loss of wolframin function (108). Diabetes mellitus development in DIDMOAD is attributed to impaired homeostasis of beta cells, and studies indicate that wolframin may help

fold proinsulin, a protein precursor of insulin, into the mature hormone that controls blood glucose levels (109). Additionally, WFS1 is up-regulated in mouse pancreatic beta cells during glucose-induced insulin secretion, whereas WFS1 knockdown in beta cells resulted in ER stress and cell dysfunction. These authors hypothesized that Wolfram syndrome thus involves chronic ER stress in pancreatic beta cells. Interestingly, a heterozygous mutation of WFS1 may explain some cases of autosomal dominant, non-syndromic sensorineural, low-frequency hearing loss (110). Sandhu et al. reported that two single nucleotide polymorphisms (rs10010131, rs6446482) are associated with risk for type 2 diabetes mellitus (111).

In contrast, WS2 localizes to the long arm of chromosome 4 (4q22–24) and is caused by mutations in the *CISD2* gene (MIM222300), which codes for an ER intermembrane protein (112). Unlike classic Wolfram syndrome, the patients—all from consanguineous Jordanian families—did not exhibit DI and also presented with severe upper gastrointestinal bleeding/ulceration (113). Chen et al. demonstrated that, in the mouse, *Cisd2* localizes to the outer mitochondrial membrane and is involved in the control of life span (114).

The third, a mitochondrial syndrome, was initially suggested by Rotig et al. in a patient with early-onset diabetes mellitus, optic atrophy and deafness, who harbored a 7.6 kb mitochondrial deletion (115). Barrientos et al. provided evidence that mutations in the 4p16 region predispose individuals to multiple mitochondrial DNA deletions in families with Wolfram syndrome (116), although Domenech et al. did not find mitochondrial DNA abnormalities in their Spanish cohort of six WS1 families (117). Hofmann et al. found, when comparing mitochondrial DNA variants identified in DIDMOAD patients with those found in LHON patients and healthy controls, that a high percentage of DIDMOAD patients harbored secondary LHON mutations, and that both DIDMOAD and LHON patients were concentrated in two different mitochondrial haplotypes (118). He thus concluded that different clusters of mitochondrial DNA variants may act as predisposing haplotypes, increasing the risk of either DIDMOAD or LHON. However, the characteristics distinguishing the three genetic subtypes have been questioned, as the *CISD2* gene of Wolfram syndrome 2 has been implicated in mitochondrial dysfunction as well (114a). As such, the relationship between either of the autosomal loci for Wolfram syndrome and mitochondrial mutations is unclear.

Treatment of Wolfram syndrome is symptomatic. The diabetes mellitus is treated with insulin. Physicians should monitor patients carefully for signs of urological complications. As wolframin is a transmembrane protein with multisystem localization, other tests to consider include dynamic pituitary gland tests, such as an insulin tolerance test and lutenising hormone releasing hormone (LH-RH) test, as well as a water deprivation test to determine posterior pituitary gland function (119). Depending

on the degree of hearing impairment, hearing loss may be managed with hearing aids or cochlear implantation. No treatment is available for the basic defect.

### Biographies

**Grace Shih** is a medical student at Vanderbilt University School of Medicine. She graduated cum laude with a BS in biology from Duke University in 2008. As a 2011–2012 Howard Hughes Medical Institute Cloister program research scholar at the National Institutes of Health, she worked in the laboratory of Brian Brooks, MD, PhD.

**Brian P Brooks** obtained his MD and PhD from the University of Pennsylvania. His residency training in ophthalmology and fellowship training in pediatric ophthalmology were completed at the University of Michigan. Dr Brooks completed a clinical genetics fellowship at the Metropolitan Washington DC Medical Genetics program centered at the National Human Genome Research Institute. Dr Brooks is one of the few physicians in the United States boarded in both ophthalmology and clinical genetics. He is currently Chief, Unit on Pediatric, Developmental, and Genetic Ophthalmology in the Ophthalmic Genetics and Visual Function Branch of the National Eye Institute. In 2010, he was awarded the Presidential Early Career Award for Science and Engineering by President Barak Obama, the nation's highest honor for young investigators.

## Glaucoma

*Janey L Wiggs*

Department of Ophthalmology, Harvard Medical School, Massachusetts Eye and Ear Infirmary,  
Boston, MA, USA

### 135.1 INTRODUCTION

The glaucomas are a leading cause of blindness in the United States. One to two percent of Americans older than age 40 years are affected with glaucoma, and each year over 10,000 are blinded by the disease (1). In the United States, the glaucomas are the second most common cause of permanent blindness and the most common cause of blindness among blacks (2). The clinical diagnosis of glaucoma does not refer to a single, distinct condition, but rather to a collection of similar appearing diseases. The glaucomas all have the same basic phenotype, which is characterized primarily by a bilateral, progressive degeneration of the optic nerve. This glaucomatous optic neuropathy causes an irreversible loss of vision, which can lead to complete blindness without proper therapy. In most cases, glaucoma is associated with elevated intraocular pressure (IOP); however approximately one-third of cases have optic nerve degeneration despite intraocular pressures in the normal range. The anatomy and physiology of the optic nerve and the structures regulating aqueous humor dynamics are important elements in the biology of glaucoma and serve as a framework for investigating its pathogenesis. The optic nerve forms a link between the neurosensory retina and the brain, and is an important segment of the visual pathway. Light is detected by the photoreceptor cells of the retina and a signal is transmitted through complex interconnections with other retinal cells to the ganglion cell layer of the retina. The axons of the ganglion cells, which collectively form the optic nerve, project to the lateral geniculate nucleus and onto the occipital cortex, where the visual input is perceived.

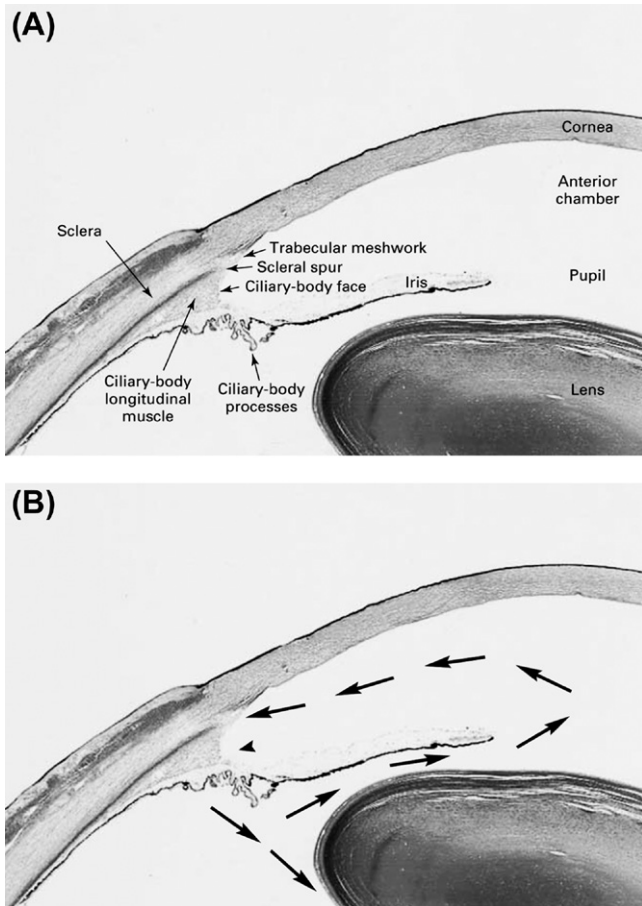

Elevated IOP is associated with most forms of glaucoma and is currently the only known modifiable risk factor for these diseases. IOP is determined by the balance between the rate of aqueous humor production and the rate of outflow from the eye. Aqueous humor is produced by the ciliary body, a tissue located posterior to the peripheral iris. The majority of the aqueous humor drains from the eye through the trabecular meshwork (TM),

a sponge-like tissue located at the iridocorneal angle, the junction of the iris and the cornea (Figure 135-1A). Current treatment strategies are all directed at lowering IOP, and in many cases, these interventions are effective at slowing or halting the progression of glaucoma. The early signs of the disease are often subtle and significant nerve damage and vision loss may occur before glaucoma is recognized by either patients or clinicians. Genetic studies of glaucoma could lead to the development of new diagnostic and therapeutic tools. The identification of glaucoma-causing genes could assist clinicians in diagnosing glaucoma before irreversible blindness occurs. Patients carrying alleles known to confer risk of severe disease could be targeted for aggressive therapy. Glaucoma genetic research could also produce gene-based therapeutic strategies and lead to the identification of alleles predicting treatment outcomes. A family history of glaucoma is well recognized as a major risk factor for the disease, (3), and both Mendelian and non-Mendelian forms of inheritance have been described. The most common adult-onset forms of glaucoma such as primary open-angle glaucoma (POAG), exfoliation syndrome glaucoma (EG) and closed-angle glaucoma have heritability consistent with that of a complex trait, while early onset forms typically exhibit Mendelian inheritance patterns (4).

This chapter is divided into four sections: (1) clinical presentation of heritable forms of glaucoma, including nomenclature and phenotypic descriptions; (2) identification of glaucoma genes using human linkage studies; (3) glaucoma genes identified from studying naturally occurring animal models; and (4) genes identified using genomic approaches.

### 135.2 CLINICAL FEATURES OF HERITABLE FORMS OF GLAUCOMA

The glaucomas are classified as two groups: primary and secondary glaucomas. Primary glaucoma is defined as isolated, idiopathic disease of the anterior chamber of the eye and the optic nerve, whereas secondary glaucoma

**FIGURE 135-1** The anterior segment of the eye. Panel A shows the major structures. Panel B shows the flow of aqueous humor through the anterior segment. Aqueous humor is produced by the ciliary body processes. It flows around the lens, then passes through the pupil and into the anterior chamber, where it nourishes the cornea before leaving the eye through the TM into the venous system. (From Alward, W. L. M. *Medical management of glaucoma*. *N. Engl. J. Med.* 1998, 339, 298–1307, with permission.)

**FIGURE 135-2** Gonioscopy. In order to view the structures of the iridocorneal angle, a gonioscopy contact lens is placed on the surface of the cornea. (Courtesy of Dr. WLM Alward, Department of Ophthalmology and Visual Sciences, The University of Iowa Hospitals and Clinics.)

is associated with known predisposing events including developmental abnormalities, systemic diseases, drug therapy, or trauma.

The primary glaucomas are further categorized by the anatomy of the junction of the iris and the cornea (the iridocorneal angle). The iridocorneal angle is the most important site of fluid drainage from the human eye. Primary glaucoma in an eye with a wide-open iridocorneal angle that allows unimpeded fluid outflow through the TM is termed primary open-angle glaucoma (POAG) (see Figure 135-1A). In glaucoma, the iridocorneal angle is narrow and aqueous humor outflow is obstructed. The vertex of the iridocorneal angle and the TM cannot be directly visualized under normal circumstances. Ophthalmologists may view this structure by placing a specialized lens directly on the cornea (Figure 135-2).

Open-angle glaucomas are further classified by the age of onset of disease (congenital; juvenile; and primary open-angle glaucoma [POAG]). Open-angle glaucoma with an onset during infancy (less than three years of age) is termed congenital glaucoma, whereas glaucoma with onset after 40 years of age is classified as POAG. Juvenile open-angle glaucoma (JOAG) has its onset at an age intermediate to that of congenital and primary open-angle glaucoma.

### 135.2.1 Primary Glaucomas

#### 135.2.1.1 Primary Open-Angle Glaucoma (POAG).

Of the many forms of glaucoma, POAG is the most common. In the Framingham Eye Study, 1.6% of subjects over 40 years of age were affected with POAG (5). The prevalence of POAG varies between ethnic populations. The prevalence of POAG in blacks is five times that in whites (2). It is a genetically complex trait that is likely to result from the effects of multiple genetic and/or environmental factors. Large pedigrees with apparent Mendelian inheritance have been reported, but typically POAG shows familial clustering without a recognized inheritance pattern (3). First-degree relatives of individuals affected with POAG have up to an eight-fold increased risk of developing POAG compared with the general public (6). Additionally, many of the clinical features of POAG are heritable quantitative traits, including cup to disc ratio and IOP (described later) (7).

**Classic Features of Primary Open-Angle Glaucoma.** In most cases, POAG is a slowly progressive and painless optic neuropathy with an associated insidious loss of visual field. Consequently, many patients are unaware that they are affected with this disease. The defining features of POAG (and of other forms of glaucoma) are characteristic optic nerve damage and loss of visual field. Many patients also have elevated IOP, although this feature is not required for the diagnosis of glaucoma. The defining clinical features of POAG are described in the following sections:

**Optic Nerve Disease.** Visual input from the retina reaches the brain through an intricate network of

neuronal connections that begins with the axonal projections of retinal ganglion cells, which unite to form the optic nerve. The axons from the ganglion cells of the entire retina converge at the posterior pole of the eye forming the head of the optic nerve, the optic disc. As they come together in the plane of the globe, the ganglion cell axons turn posteriorly to exit the eye forming an indentation in the optic disc called the optic cup. Characteristics of the optic nerve (including the size of the optic cup) may be observed directly by looking through the pupil with an ophthalmoscope. A healthy optic disc is pink, and the ratio of the diameter of the optic cup to that of the optic disc averages 0.4 (Figure 135-3A). A defining feature of glaucoma is the progressive loss of the ganglion cell layer of the retina and the axons that form the optic nerve. As optic nerve tissue is lost, the optic cup grows larger, increasing the cup to disc ratio (Figure 135-3B).

**Loss of Visual Field.** Visual field is the area concurrently seen by a fixed eye. The topographical organization of the visual input is maintained during transmission from the retina to the visual cortex. The optic nerve damage caused by glaucoma destroys some of the connections between the retina and the brain, which causes defects in the visual field. The portion of the optic nerve that conveys peripheral and paracentral vision is preferentially affected by glaucoma. Consequently, individuals affected with glaucoma most commonly have constricted visual fields (peripheral blindspots with central vision spared). Because central vision is generally preserved until late in the course of glaucoma, patients with significant visual field losses frequently have good visual acuity.

Perimetry is the systematic measurement of visual fields. Patients fix one eye on a target directly forward, while the other eye is covered with a patch. Test objects, such as light sources or examiner's fingers, are then presented to the fixed eye at various positions. Patients signal when they see these objects, allowing their visual field to be mapped. Visual fields may be measured manually or with automated equipment using static or kinetic targets.

**Elevated Intraocular Pressure (IOP).** The anterior and posterior chambers of the eye are bathed in nutrient- and oxygen-rich aqueous humor, which provides nourishment to the avascular, translucent structures of the lens and cornea. Aqueous humor is secreted by the epithelium of the ciliary body and flows around the lens, through the pupil, and across the anterior surface of the iris to the angle formed between the cornea and iris, the iridocorneal angle (see Figure 135-1B). The aqueous humor drains from the eye through the TM (trabecular meshwork), which is located at the vertex of the iridocorneal angle. Aqueous humor passes through the TM to the venous circulation through a network of vessels beginning with Schlemm's canal. Although there are other pathways of drainage, the TM route accounts for the majority of outflow in human eyes.

The chief determinants of IOP are the rate of aqueous humor production by the ciliary body and the rate of aqueous humor outflow through the TM. In normal individuals the balance between aqueous humor production and outflow results in a mean IOP of approximately 15.5 mmHg. Two standard deviations above the mean IOP (20.5 mmHg) are generally accepted to be the upper limit of the normal range of pressure. There is

**FIGURE 135-3** Optic nerve head. (A) The optic nerve head of normal individuals has a characteristic pink color and an average cup to disc ratio of 0.4. (B) The optic nerve head of a patient with endstage glaucoma is excavated and has a cup to disc ratio approaching 1.0. There is a pale appearance in the areas where nerve tissue has been lost. (Courtesy of Dr. W.L.M. Alward, Department of Ophthalmology and Visual Sciences, The University of Iowa Hospitals and Clinics.)

a considerable overlap between the range of IOPs in glaucoma patients and the general population. Patients with IOPs above the normal range have an increased risk of developing glaucoma, yet an elevated IOP is not sufficient for a diagnosis of glaucoma. IOP also varies diurnally, with peak pressures usually occurring in the morning. IOPs above 21 mmHg are generally considered elevated.

Studies have shown that elevation of IOP in glaucoma is primarily due to increased resistance to aqueous humor outflow through the TM (8). The biological mechanisms of disease in glaucoma are poorly understood. The processes that lead to optic nerve damage and vision loss are unclear. It is generally accepted that IOP has a significant role in the pathogenesis of POAG and other forms of glaucoma. Currently, elevated IOP is the only modifiable glaucoma risk factor and all available glaucoma treatments attempt to slow the progress of disease by lowering IOP.

Elevated IOP is often associated with glaucoma. Some individuals develop optic nerve disease and visual field loss characteristic of glaucoma without ever having measurably high IOP ('normal tension' glaucoma). Conversely, others with elevated IOP may never develop the defining features of glaucoma. Elevated IOP in the absence of optic nerve disease and visual field loss is known as ocular hypertension. For most patients, high IOP is an important risk factor for the development of glaucoma and treatment of elevated IOP reduces this risk.

**135.2.1.2 Juvenile-Onset Primary Open-Angle Glaucoma (JOAG).** JOAG is a relatively rare subset of glaucoma representing less than 1% of total cases (9). JOAG has been defined as a severe form of POAG, which is characterized by onset of disease between three and 40 years of age and highly elevated IOPs, sometimes over 50 mmHg. The heredity of JOAG is much more evident than that of POAG; because of the early age of disease onset, several generations of affected family members are usually alive and available for examination. Consequently, many large JOAG pedigrees have been described which exhibit obvious autosomal dominant inheritance and a high, but incomplete penetrance.

**135.2.1.3 Normal Tension Glaucoma (NTG).** Some glaucoma patients develop optic nerve damage and visual field loss without ever having a high IOP measurement. This form of glaucoma is known as normal tension glaucoma (NTG). NTG patients share features of POAG (open iridocorneal angles, optic neuropathy, and visual field loss), but have IOP that consistently remains within the 'normal' range. A standard set of diagnostic criteria for NTG does not exist, however, the Collaborative Normal-Tension Glaucoma Study Group has used the following strict definition of NTG. Patients are diagnosed with NTG if they have;

1. optic disc abnormalities and visual field defects consistent with glaucoma,
2. no history of IOP over 24 mmHg, and
3. a diurnal IOP with a median of 20 mmHg or less with only one measurement of 23 or 24 mmHg (based on 10 measurements between 8 am and 6 pm over two days) (10).

Population-based prevalence studies have suggested that NTG is a common form of glaucoma, potentially accounting for up to 30% to 60% of cases in various populations (11).

At present, it is unclear whether NTG and high-pressure glaucoma represent different ends of a single spectrum of disease or are distinct conditions. Studies suggest that several clinical signs are more frequently found in NTG, including optic disc hemorrhages, specific changes in the appearance of the optic nerve head, and characteristic types of visual field defects (12). Other factors that have been investigated for an association with NTG include age, female gender and Asian ethnicity and vasospasm (13).

#### **135.2.1.4 Developmental Glaucomas.**

**135.2.1.4.1 Primary Congenital Glaucoma.** The congenital glaucomas are typically associated with severe disease and are usually diagnosed at birth. Primary congenital glaucoma (PCG) is characterized by isolated abnormalities of the iridocorneal angle that lead to decreased aqueous outflow and elevated IOP. PCG is a common form of childhood glaucoma and accounts for approximately 22% of total cases (14). The average prevalence of PCG is 1:10,000 births, although extreme variation with ethnic background (ranging from 1:1250 to 1:22,000) has been reported (14).

The classic signs of PCG are tearing, photophobia, and lid squeezing. The cornea may be cloudy or exhibit breaks in the corneal endothelium known as Haab's striae. These signs, which may be bilateral or unilateral, are all due to elevated IOP. The structure of the infantile eye is immature and it stretches in response to high IOP. Consequently, patients affected with congenital glaucoma often have markedly enlarged eyes, termed buphthalmos (Greek for 'ox eye', Figure 135-4). After three years of age, elevated IOP will no longer cause the eye to enlarge. The high IOP of PCG may cause severe optic neuropathy and profound vision loss unless treatment is urgently provided.

**135.2.1.4.2 Anterior Segment Dysgenesis Syndromes.** Most of the structures comprising the 'anterior segment' of the eye (iris, trabecular meshwork, anterior chamber, aqueous humor cornea and iridocorneal angle) arise developmentally from the cranial neural crest, and disruption of these developmental processes results in abnormal formation of the trabecular meshwork and other structures necessary for fluid removal, causing an early-onset form of glaucoma (typically between the ages of 10 to 20). These developmental disorders are usually inherited as autosomal dominant traits and may be associated with systemic abnormalities (15). For example, in addition to ocular dysgenesis, patients affected by Axenfeld-Rieger syndrome have abnormal

**FIGURE 135-4** Buphthalmos. Enlarged eyes caused by elevated IOP in congenital glaucoma. (Courtesy of Dr. W.L.M. Alward, Department of Ophthalmology and Visual Sciences, The University of Iowa Hospitals and Clinics.)

teeth and hearing loss (16). Other glaucomas of childhood are associated with additional ocular or systemic developmental abnormalities. Reviewed in Refs. (17–20).

## 135.2.2 Secondary Glaucomas

**135.2.2.1 Pigment Dispersion Syndrome (PDS)/ Pigmentary Glaucoma (PG).** Pigment dispersion syndrome (PDS) is an ocular condition in which pigment granules from the iris are released into the anterior chamber of the eye. A subset of PDS patients develop signs of glaucoma related to the dispersal of pigment. This secondary glaucoma is known as pigmentary glaucoma (PG) and shares many features with POAG (elevated IOP, optic neuropathy, and visual field loss). The clinical presentations of PDS/PG have been studied for over 100 years (21), and there is a rich history of observation and experimentation that has contributed to our knowledge of these conditions (22,23). The iris in most patients with PDS has a concave or ‘back-bowed’ shape, which appears to be an important factor in the pathogenesis of the disease (22). Liberation of pigment from the iris produces the classic features of PDS, including defects in the iris visible by transillumination and accumulation of released pigment on the corneal endothelium (Figure 135-5), trabecular meshwork, lens and zonules.

PDS is a common condition that affects up to 2.5% of the general population and may be more common in young nearsighted (myopic) men (24). PDS has a peak incidence before 30 years of age and becomes less common with age. Deeper anterior chambers, which are more common in myopic eyes, may promote an abrading configuration of the iris–lens surfaces. The normal, progressive growth of the lens tends to shallow the anterior chamber, which normalizes the configuration of the iris and reduces the risk of PDS with age.

A significant fraction of PDS patients develop glaucoma secondary to pigment dispersion. The fraction

**FIGURE 135-5** Krukenberg's spindle. Dispersed iris pigment that accumulates on the corneal endothelium (known as a Krukenberg's spindle) is a sign of PDS/PG. (Courtesy of Dr. W.L.M. Alward, Department of Ophthalmology and Visual Sciences, The University of Iowa Hospitals and Clinics.)

of PDS patients that eventually progress to pigmentary glaucoma (PG) is as high as 35% to 50% in glaucoma clinics and tertiary care centers (25). A recent population based study from Olmsted County, Minnesota found that 10% of PDS patients had developed glaucoma over 5 years, and 15% over 15 years (26). The pathophysiological basis of the progression from pigment dispersion to glaucoma is largely unknown. The simplest explanations suggest that pigment accumulation in the TM impedes aqueous humor outflow, causing IOP elevation and subsequent glaucoma (27). Pedigrees with PDS segregating as an autosomal dominant trait have been described (28) and several loci have been identified, although causative genes have not yet been characterized.

**135.2.2.2 Exfoliation Syndrome/Exfoliative Glaucoma.** Exfoliation syndrome is a systemic condition in which fibrillar protein is deposited in tissues throughout the body, including the eye (29). Although the exfoliative material is also produced in many other organs, its pathology appears to be limited to the eye. The origin of the material is not completely understood, but may develop because of extracellular matrix degeneration and compromise of associated vasculature (30). In the eye, the material accumulates on all the structures of the ocular anterior segment. Exfoliative material on the lens is distributed in a characteristic ‘bull's-eye’ pattern (Figure 135-6). This annular configuration is generated by the iris as it rubs along the lens during normal dilation and constriction of the pupil. Exfoliative material is brushed away in a ring-shaped zone corresponding to the excursion of pupillary margin. Collections of exfoliative material may also be observed on the surfaces of the iris, cornea, and TM, along with pigment granules from the iris (probably released by abrasion between the iris and the lens). These signs of exfoliation syndrome are frequently extremely asymmetric.

**FIGURE 135-6** Lens appearance in exfoliation syndrome. Exfoliation material accumulates on the anterior lens capsule. The material is removed by abrasion with the iris during normal dilation and constriction of the pupil forming a 'bull's eye' pattern. (Courtesy of Dr. W.L.M. Alward, Department of Ophthalmology and Visual Sciences, The University of Iowa Hospitals and Clinics.)

The prevalence of exfoliation syndrome varies dramatically with ethnic background and increases with age (31). Exfoliation syndrome is common in Scandinavian and Mediterranean countries with a prevalence of up to 21% and is associated with a significant fraction of open-angle glaucoma in these areas. Recent studies indicate that residence in Northern latitudes is a risk factor for developing the syndrome (32).

Patients with exfoliation syndrome are at high risk of developing a secondary glaucoma (22% to 82%) (33). Exfoliative glaucoma is associated with similar pressure-related optic nerve damage and visual field loss to POAG. Patients affected with exfoliative glaucoma tend to be older than POAG patients and may present with IOP that becomes rapidly elevated.

In most cases of exfoliative glaucoma, the iridocorneal angles are open and elevated IOP is caused by changes in the TM related to the accumulations of exfoliative material. The amount of exfoliative material appears to correlate with the development of glaucoma (34), but its accumulation alone is not sufficient to cause glaucoma. The presence of exfoliative material may cause TM endothelial cells to become dysfunctional as they attempt to remove the exfoliative material by phagocytosis. The iridocorneal angle is generally open in exfoliation syndrome. Owing to an associated weakness in the suspension of the lens, patients with exfoliation syndrome have a predisposition for subluxation of the lens. Dislocated lenses may press the iris anteriorly and cause a form of closed-angle glaucoma-associated with exfoliation syndrome.

There is evidence from epidemiological studies that genetic factors significantly contribute to the pathogenesis of exfoliation syndrome as described earlier. Individuals of certain ethnic backgrounds are at higher risk

for developing exfoliation syndrome than others. Some families with inherited exfoliation syndrome have been described, and twin studies have provided support for a genetic basis of this disease (35,36).

### 135.2.3 Angle-Closure Glaucoma

The normal, flat configuration of the iris results in a wide-open iridocorneal angle allowing aqueous humor outflow through the TM (see Figure 135-1B). A number of anatomic abnormalities, however, can cause the iris to become apposed to the TM, resulting in a narrowed or closed iridocorneal angle and obstructed aqueous outflow. Angle-closure glaucoma is due to the elevated IOP associated with acute or chronic obstruction of aqueous outflow by a visible occlusion of the iridocorneal angle. The prevalence of angle-closure glaucoma varies greatly between ethnic backgrounds. Angle-closure glaucoma is extremely common among Eskimos and Asians (37).

**135.2.3.1 Mechanism of Angle Closure.** The relative position of the lens and the iris change as the pupil dilates and constricts. In susceptible individuals, the lens may become apposed to the pupil margin and obstruct the normal flow of aqueous humor through the pupil. This phenomenon, known as pupillary block, is the most common cause of angle-closure glaucoma. Pressure builds in the posterior chamber as aqueous humor collects behind the iris and eventually causes the iris to bow forward. This convex configuration of the iris brings the peripheral iris in close proximity to the TM causing a narrow or closed iridocorneal angle. Anatomic features of the eye may promote the development of angle closure. An enlarged lens may cause angle-closure by pushing the iris anteriorly against the TM (phacomorphic angle-closure). Similarly, abnormalities of the attachment of the iris to sclera at the iridocorneal angle may alter the configuration of the iris to favor the development of angle-closure.

Several environmental factors or physical characteristics of the eye may also predispose angle-closure by the pupillary block mechanism. In small, far-sighted (hyperopic) eyes, the anterior segment of the eye is 'crowded' with normal-sized lens and iris tissue. In such eyes, the relatively large lens is more likely to obstruct the pupil. With age, the lens gradually grows in size, further favoring the development of pupillary block. Some medications, such as topiramate, or other sulfa derivative drugs can in some individuals cause angle-closure glaucoma. In these drug-related cases both eyes typically develop symptoms, while in the lens-related cases using only one eye is affected at a given time.

Family and twin studies suggest that angle-closure glaucoma has a significant heritability (38), however genetic risk factors have not been identified for this condition.

### 135.3 IDENTIFICATION OF GLAUCOMA GENES USING LINKAGE ANALYSIS

Early-onset forms of glaucoma are amenable to linkage studies. Gene discovery using a positional cloning/linkage approach requires large affected pedigrees with well-defined inheritance. The early-onset glaucomas are inherited as either autosomal dominant or autosomal recessive traits. Disease onset during childhood results in affected pedigrees sufficiently large for a linkage-based approach to identify a genomic region harboring the causative gene. Some adult-onset (>age 40) glaucoma pedigrees have familial disease distribution suggestive of autosomal dominant or autosomal recessive inheritance patterns.

#### 135.3.1 Nomenclature of Glaucoma Loci

The nomenclature committee of the Human Genome Organization (HUGO) has designated a system for naming glaucoma gene loci (<http://www.gene.ucl.ac.uk/nomenclature>). The prefix 'GLC' indicates a glaucoma gene locus. The type of glaucoma is indicated by a subsequent number, where a '1' indicates open-angle glaucoma, a '2' indicates closed angle glaucoma, and a '3' indicates congenital glaucoma. Finally, a suffix letter is attached to each new glaucoma loci in chronological order of discovery. For example, GLC1A was the first open-angle glaucoma locus to be discovered. There is no systematic nomenclature for loci associated with secondary or developmental forms of glaucoma. The currently known primary and secondary glaucoma loci defined by genetic linkage studies are indicated in Table 135-1.

#### 135.3.2 Myocilin (MYOC, OMIM #601652); Juvenile Open-Angle Glaucoma

Using a large juvenile open-angle glaucoma pedigree, linkage analysis identified a chromosome 1q23 disease locus termed GLC1A, (39). Fine mapping and gene resequencing identified the MYOC gene as the GLC1A causative gene (40). MYOC encodes a protein (myocilin) previously identified as a steroid-responsive protein in TM cells challenged with glucocorticoids to simulate the conditions of steroid-induced ocular hypertension (OHT). Myocilin has an unknown function. Sequence analysis of the myocilin gene predicts a 57-kD protein with homology to olfactomedin, (41). The myocilin protein is targeted for secretion by a signal sequence and, the carboxy-terminus contains a consensus sequence, which may direct the protein to peroxisomes. Although Myocilin appears to be primarily associated with juvenile open-angle glaucoma, some mutations cause later onset primary open-angle glaucoma (42,43).

The glaucoma-associated mutations are concentrated in the olfactomedin-domain encoded by exon 3 of myocilin (44). The function of the olfactomedin domain is

unknown, and the significance of the clustering of myocilin mutations remains unclear.

More than 40 mutations have been identified in POAG patients. However, a single mutation (Gln368Stop) is associated with nearly half of all cases of myocilin-associated glaucoma (42). Haplotype analysis suggests that the Gln368Stop mutation arose in a single founder and patients with this mutation are distantly related to this common ancestor. If the prevalence of the Gln368Stop mutation in study populations is representative of its frequency in the general public, this defect in myocilin is one of the most common causes of eye disease with a known molecular defect. Myocilin mutations cause a dominant negative effect, and loss of myocilin function does not cause glaucoma (45).

#### 135.3.3 Optineurin (OPTN, OMIM #602432)

**135.3.3.1 Optineurin and Normal Tension Glaucoma.** In normal tension glaucoma, the optic nerve degenerates despite intraocular pressure in the normal range (less than 22mmHg). Using standard linkage approaches and a large pedigree affected by normal tension glaucoma, a gene for normal tension glaucoma was mapped to 10p14–p15 (GLC1E) (46). Screening candidate genes in this region revealed a mutation (Glu50Lys) that was responsible for the NTG affecting this pedigree (47). Subsequent studies have confirmed the association of the Glu50Lys optineurin variation with NTG, but other DNA sequence variants in this gene have not been consistently associated with the disease (48–50). Optineurin participates in the TNF- $\alpha$  mediated apoptotic pathways, which may explain its association with normal tension glaucoma, as this is a form of glaucoma with increased susceptibility to optic nerve degeneration caused by apoptosis.

#### 135.3.4 Cytochrome P450 (CYP1B1); Primary Congenital Glaucoma

Primary congenital glaucoma (PCG) is most commonly inherited as an autosomal recessive trait, although sporadic and autosomal dominant forms have also been reported (51).

Linkage studies using large pedigrees mapped a PCG-causing gene to the GLC3A locus on chromosome 2p21 (52). Subsequently, mutations in cytochrome P450 1B1 (CYP1B1), have been identified in families world-wide (53,54). Two other congenital glaucoma loci have been mapped (55,56) and one other disease causing gene, LTBP2 has been recently identified (57). LTBP2 maps to 14q24.1, 1.3 Mb from the boundary of GLC3C as it was originally defined. It is possible that a second congenital glaucoma gene resides within this region (Table 135-1).

**135.3.4.1 CYP1B1 Genotype–Phenotype Associations.** CYP1B1 mutations causing congenital glaucoma

<sup>a</sup>LTBP2 maps 1.3 Mb from the originally defined GLC3C linkage interval and it is possible that a second congenital glaucoma gene resides in this region. ASD, anterior segment dysgenesis; JOAG, juvenile open-angle glaucoma; IOP, intraocular pressure; NTG, normal tension glaucoma; PDS, pigment dispersion syndrome; PG, pigmentary glaucoma; POAG, primary open-angle glaucoma.

cause a loss of protein function. Affected individuals with mutations in *CYP1B1* demonstrate significant variation in disease severity both among and between families that may be mutation specific, secondary to background haplotype effects, or due to effects of hypothetical modifier genes (58). Tyrosinase is a modifier of disease severity in mice (59), but tyrosinase gene variants do not appear to influence disease expressivity in humans (60).

**135.3.4.2 CYP1B1 Function.** The *CYP1B1* protein sequence contains several conserved domains that are likely to be functionally important, including heme-binding and hinge regions (61). Many of the *CYP1B1* mutations are clustered in conserved heme-binding and hinge regions, or cause premature termination that eliminates these structures (62).

*CYP1B1* is a member of a family of cytochrome P450 genes known to encode enzymes that metabolize and detoxify both endogenous and exogenous molecular, although their activity is not limited to detoxification. The cytochrome P450 enzymes have been postulated to have a role in development by influencing the metabolism of molecules

necessary for specific developmental processes (63). Two specific substrates of *CYP1B1* (estradiols and retinoic acid) could contribute to ocular development and specifically to the development of the ocular anterior segment.

#### 135.3.4.3 Anterior Segment Dysgenesis and Developmental Regulatory Genes.

**135.3.4.3.1 PITX2, FOXC1, LMX1B, PAX6; Developmental Glaucoma and Anterior Segment Dysgenesis.** The structures of the ocular anterior segment (iris, trabecular meshwork, anterior chamber, aqueous humor, and cornea) arise from the cranial neural crest. Abnormalities in genes controlling neural crest development can result in abnormal formation of the anterior segment structure involved in glaucoma. These developmental disorders are usually inherited as autosomal dominant traits and may be associated with systemic abnormalities (17). For example, patients affected by Axenfeld–Rieger syndrome have abnormal teeth formation in addition to ocular abnormalities (64). Several loci and two genes coding for transcription factors (paired-like homeodomain transcription factor 2 [*PITX2*] at

*RIEG1*, (15,16), and forkhead box C1 [*FOXC1*] at *RIEG3*, (65,66)) have been associated with Axenfeld–Rieger syndrome. A spontaneous *FOXC1* mutation is also the cause of the congenital hydrocephalus mouse (ch) that exhibits multiple defects of the skull and skeleton, kidneys, ureters and eyes (67,68). Other genes causing developmental glaucoma are *PAX6* (Aniridia) (69) and *LMX1B* (nail–patella syndrome and anterior segment dysgenesis) (70) and *PITX3* (anterior segment dysgenesis and cataracts) (71). Interestingly, the developmental glaucoma syndromes frequently exhibit variable expressivity, with glaucoma only occurring in about 50% of cases overall (72). The cause of the variable expressivity is not known; however, it may be secondary to modifier genes or stochastic effects (73).

## 135.4 GENES CAUSING GLAUCOMA IN ANIMAL MODELS

One approach for finding candidate genes for human glaucoma is to study animals with hereditary forms of glaucoma. The assumption of this approach is that genes important to animal forms of glaucoma will also contribute to human glaucoma. There are also valuable animal models relevant to glaucoma with inducible phenotypes. A full discussion of all of these models would be beyond the scope of this chapter. In the following sections the genes responsible for naturally occurring forms of glaucoma will be described in mice, dogs and zebrafish.

### 135.4.1 Mice

The DBA/2 lineage of mice, including DBA/2J (74–77), DBA/2NNia (78–80), and AKXD-28/TyJ (81) all develop age-related forms of glaucoma that include iris disease, increased IOP, and retinal ganglion cell loss. The disease-causing mutations have been identified in DBA/2J (74,75). The glaucomatous iris disease of DBA/2J mice results from a digenic interaction of mutations in two genes encoding melanosomal proteins, *Tyrp1* and *Gpnmb*. The features of DBA/2J eyes bear particular resemblance to human pigment dispersion syndrome and pigmentary glaucoma, and therefore, are excellent candidates for the causes of these diseases. Mutations in human *GNMB* or *TYRP1* have not been identified (74,82).

### 135.4.2 Dogs

A colony of Beagle dogs with the anatomic characteristics of POAG, including elevation of intraocular pressure and optic nerve disease, was used for a series of genetic linkage experiments that identified a homozygous missense change in *ADAMTS10* as the responsible mutation (83). In humans, homozygous mutations in *ADAMTS10* cause lenticular myopia, ectopia lentis, glaucoma, spherophakia and short stature, features of the Weill–Marchesani

syndrome (84). Mutations in *ADAMTS10* have not been associated with POAG in humans.

### 135.4.3 Zebrafish

A forward-genetic screen for adult ocular abnormalities in zebrafish identified *bugeye*, with phenotypic features related to glaucoma phenotype including enlarged eyes with myopia, elevated IOP, and damage to retinal ganglion cells. Using linkage analysis nonsense mutations in low density lipoprotein receptor-related protein 2 (*lrp2*) were identified in mutant fish (85). *Lrp2* is a large transmembrane protein of the low density lipoprotein (LDL)-receptor related protein (*Lrp*) family and participates in receptor-mediated endocytosis. A number of ligands bind the receptor, including Sonic hedgehog and Bone morphogenetic protein 4, vitamin and hormone binding proteins, apolipoproteins, (86). *Lrp2* is expressed in the zebrafish eye and particularly in the retinal pigment and ciliary epithelial cells (85). The ciliary epithelial cells have a critical role in production of aqueous humor and in intraocular pressure dynamics. In humans, mutations in *LRP2* cause the rare Donnai–Barrow syndrome (87), characterized by agenesis of the corpus callosum, diaphragmatic hernia, sensorineural deafness, hypertelorism, buphthalmia (enlarged eye globes) and high myopia.

Forms of glaucoma have also been described in a wide variety of other animal species, although genes have not yet been associated with these forms of glaucoma. These include the monkey (88), cat (89), horse (90), rabbit (91), quail (92), and turkey (93). With the increasing knowledge of a wide variety of animal genomes (94), the hereditary basis of these glaucomas is increasingly approachable.

## 135.5 IDENTIFICATION OF GLAUCOMA GENES USING GENOMIC APPROACHES

Most human patients with glaucoma are affected by the adult-onset forms of the disease, primary open-angle glaucoma (POAG), exfoliation glaucoma (EG), and angle-closure glaucoma. The genetic and phenotypic complexity of these conditions complicates genetic linkage approaches used to identify causative genes. Recent advances in molecular genetics and genomics have supported the genetic study of common forms of adult-onset glaucoma. In particular, the annotation of the human genome sequence and the development of the HapMap (95) have facilitated genome-wide association studies to identify genes contributing to ocular quantitative traits related to glaucoma pathogenesis (cup/disc ratio, CDR; optic nerve size and central corneal thickness, CCT), as well as genes associated with exfoliation syndrome and primary open-angle glaucoma. Table 135-2 lists the genes identified using genome-wide association studies as associated with common forms of glaucoma.

**TABLE 135-2** Recent Genome-Wide Association Studies Identifying Significant SNP Associations ( $p < 5 \times 10^{-8}$ ) for Common Forms of Glaucoma and Related Quantitative Traits

### 135.5.1 Ocular Quantitative Traits (Cup/Disc Ratio); Optic Nerve Size and Central Corneal Thickness

Optic nerve parameters such as disc area and CDR are highly heritable and show substantial variation in human populations. Using normal populations, genome-wide analysis of ocular quantitative traits has led to the identification of *CDKN2BAS* and *SIX1SIX6* as genetic risk factors contributing to the CDR (96), and the *ATOH7* gene as an important determinant of optic nerve size (97). Using a similar approach, genetic factors contributing to central corneal thickness (CCT) have been identified in populations from around the world (98–101). CCT is one of the most heritable of the ocular quantitative traits. Many of the genes associated with CCT seem to be population specific, although several, including *ZNF469* and *COL8A2* have been identified in ethnically diverse populations (98,101).

**135.5.1.1 Exfoliation Syndrome.** Using a large case/control sample from Iceland, a genome-wide association study identified *lysyl oxidase-like 1* (*LOXL1*) as a major genetic risk factor for exfoliation syndrome (102), with a population-attributable risk of more than 99%. This result has been replicated in populations throughout the

world (29). *LOXL1* risk alleles are present in the majority of cases, but are also highly prevalent in controls, indicating that *LOXL1* genetic risk factors are necessary but not sufficient for the disease, and that other genetic and/or environmental factors are required for disease development (103). Recent studies suggest that the *LOXL1* genetic variants associated with disease cause decreased gene expression (104). *LOXL1* is a member of the lysyl oxidase family of proteins that catalyze the polymerization of tropoelastin to form the mature elastin polymer (105) and contribute to the spatial organization of elastogenesis.

**135.5.1.2 Adult Onset Primary Open Angle Glaucoma (POAG).** Recently, several genome-wide association studies for POAG have been completed. Using 1263 cases and over 34,877 controls from Iceland, DNA sequence variants in the *CAV1/CAV2* gene region associated with POAG (106), and this association has been replicated in a study of Caucasian cases and controls from the US (GLAUGEN) (107). A study of 590 advanced glaucoma cases and 3956 controls from Australia identified association between the SNPs located in the genomic regions containing the *CDKN2BAS* (previously associated with CDR) and *TMCO1* genes and POAG (108,109). These genes only account for a small proportion of POAG in the general population suggesting that additional POAG genes await discovery (110).

**135.5.1.3 Primary Angle-Closure Glaucoma.** Primary angle-closure glaucoma has a significant heritability, and the ocular quantitative traits related to angle-closure glaucoma, in particular axial length, are also highly heritable (38). These observations suggest that genetic factors could contribute to the development of this form of glaucoma, but genes have not yet been associated with common forms of this condition (111).

## 135.6 CONCLUSION

During the past decade, a number of new genes associated with glaucoma have been identified and future studies will likely identify many more. The identification of glaucoma genes will be the first step toward the development gene-based screening and diagnostic tests allowing for the identification of individuals at risk for disease before irreversible blindness occurs. The identification of genes contributing to glaucoma will also provide new insight into the molecular events underlying the disease pathophysiology suggesting novel therapeutic approaches. In particular genes that predispose to optic nerve disease in glaucoma could identify new targets for neuroprotective therapies that may delay or even prevent blindness associated with glaucoma.

## Biography

Janey L Wiggs, MD, PhD, is a physician scientist at the Massachusetts Eye and Ear Infirmary (MEEI) and Harvard Medical School (HMS). She currently holds the appointment of Associate Professor of Ophthalmology at Harvard Medical School and is the Associate Chief for Clinical Research in Ophthalmology at the Massachusetts Eye and Ear Infirmary. Dr Wiggs received her BA and PhD degrees in biochemistry from the University of California at Berkeley and her MD degree from Harvard Medical School. She did post-doctoral training in molecular genetics at the Massachusetts Eye and Ear Infirmary under the direction of Dr Ted Dryja. She also completed an ophthalmology residency at the Massachusetts Eye and Ear Infirmary and fellowship training in glaucoma and in medical genetics and is board certified in both Ophthalmology and Medical Genetics. Dr Wiggs' research program is focused on the discovery and characterization of genetic factors that contribute to the blinding eye disease glaucoma and is funded by the National Eye Institute (NEI) as well as other nonprofit foundations. She is the co-chair of the US-INDO joint working group (NEI) and is a member of the NEI eyeGENE consortium. Dr Wiggs currently serves on the editorial boards of *Investigative Ophthalmology* and *Visual Science (IOVS)*, *Archives of Ophthalmology* (Section Editor for Molecular Genetics), *Molecular Vision*, and the *Journal of Glaucoma*. She is a member of the scientific advisory board for the Glaucoma Research Foundation and is a past member of the National Advisory Council of the National Eye Institute.

# 136

## Defects of the Cornea

*R Krishna Sanka, Elmer Tu, and Joel Sugar*

University of Illinois at Chicago, Department of Ophthalmology and Visual Sciences,  
Chicago, IL, USA

### GLOSSARY

**Corneal dystrophy** – With exceptions, a group of inherited corneal diseases that are typically autosomal dominant, are not usually associated with other ocular or systemic abnormalities, are bilateral, commonly involve the central cornea, and progress with advancing age.

**Glaucoma** – A group of diseases that have in common a characteristic optic neuropathy with associated visual field loss for which elevated intraocular pressure is one of the primary risk factors.

**Keratoconus** – A condition of conical protrusion of the cornea associated with central stromal thinning and irregularity of the corneal surface, as well as anterior stromal scarring and deep stromal fine striations. The abnormal shape can cause visual distortions.

**Laser-assisted in situ keratomileusis (LASIK)** – A surgery that uses an excimer laser to reshape the cornea of the eye in order to change focusing power and correct vision.

**Nystagmus** – An involuntary, rhythmic oscillation of the eyes.

**Penetrating keratoplasty** – Replacement of the host cornea with surgical transplantation from a donor eye. This term is now commonly used to refer to a full thickness corneal transplantation, whereas lamellar keratoplasty is used to refer to a partial thickness corneal transplantation.

**Phototherapeutic keratectomy (PTK)** – A surgery that uses an excimer laser to treat various ocular disorders by removing tissue from the cornea. It allows the removal of superficial corneal opacities and surface irregularities. The goal is to produce a smoother and clearer cornea, and not necessarily to reduce dependency upon eyeglasses or contact lenses.

**Strabismus** – A visual disorder where the eyes are misaligned and point in different directions. This can be caused by abnormalities in binocular vision or by anomalies of neuromuscular control of ocular motility. The misalignment may be intermittent or constantly present.

### 136.1 INTRODUCTION

Defects of the cornea can play an important role in clinical genetics, because of the relative ease with which abnormalities can often be detected using simple instruments such as a hand light or the ophthalmoscope. More subtle changes can be detected on examination using the slit lamp biomicroscope or other non-invasive imaging techniques allowing rapid screening, phenotypic categorization and correlation with the molecular genetic findings.

The following discussion reviews first the corneal dystrophies, followed by corneal changes associated with inherited systemic disorders, and finally isolated congenital corneal anomalies.

### 136.2 DYSTROPHIES

#### 136.2.1 Definition

As a group, the corneal dystrophies tend to be autosomal dominant in inheritance, are not usually associated with other ocular or systemic abnormalities, are bilateral, commonly involve the central cornea, and progress with advancing age. Some changes are usually present in the first few decades of life. Exceptions to all of these generalizations exist and are discussed as the specific entities are reviewed. On examination, these diseases are often limited to a single layer of the cornea, and are traditionally discussed in groups according to their layer of corneal involvement. Significant advances in the understanding of molecular genetic defects in many of these disorders allow for better grouping and classification (1,2).

These advances in genetic analysis have made it difficult to maintain the historical dystrophy classification system. In 2005, the International Committee for Classification of Corneal Dystrophies (IC3D) was formed to revise the nomenclature and include information regarding genetic analysis, histopathology, and phenotypic

description (Tables 136-1) (3). Their classification system continues to organize corneal dystrophies anatomically by the corneal layer that is chiefly affected. Depending on the evidence available to support its existence, each dystrophy is assigned to a category as follows:

- Category 1: A well-defined corneal dystrophy in which the gene has been mapped and identified and specific mutations are known.
- Category 2: A well-defined corneal dystrophy that has been mapped to one or more specific chromosomal loci, but the gene(s) remains to be identified.
- Category 3: A well-defined corneal dystrophy in which the disorder has not yet been mapped to a chromosomal locus.
- Category 4: This category is reserved for a suspected new, or previously documented, corneal dystrophy, although the evidence for it being a distinct entity is not yet convincing.

### 136.2.2 Epithelial and Subepithelial Dystrophies

Epithelial dystrophies affect the corneal epithelium and its basement membrane, most often causing painful recurrent epithelial erosions. Subepithelial erosions cause decreased vision and can also be accompanied by painful erosions.

Epithelial basement membrane dystrophy (including map-dot-fingerprint dystrophy, recurrent erosive corneal dystrophy, Cogan microcystic dystrophy) (a minority of cases are IC3D Category 1).

The hallmarks of epithelial basement membrane dystrophy (EBMD) are cysts and putty-like opacities in the corneal epithelium with irregular gray lines in a map-like configuration and/or fingerprint-like ridges in the deep epithelium (Figure 136-1). Often asymptomatic, they may still produce symptoms by making the corneal epithelial surface irregular and thus blurring vision. More commonly, they cause spontaneous erosion or sloughing of the epithelium, leading to sudden severe pain. Characteristically, affected patients report being awakened from their sleep by severe ocular pain and foreign body sensation. Examination at this time reveals a defect in the corneal epithelium that is often surrounded by loose, redundant epithelium, which may heal spontaneously over several hours. Onset of the disorder can be at any age but most commonly is after the second or third decade. Symptoms may occur frequently for months to years and then abate completely. Usually, no long-term visual difficulties occur and no scarring takes place unless secondary infection occurs during an erosive episode. The major differential diagnosis is between this disorder and a secondary form that occurs as an early sign of corneal edema from other causes. It may also be confused with Meesmann dystrophy. The disorder appears to be due to altered production of epithelial basement

membrane with multilaminated and irregular as well as abnormally positioned basement membrane and fibrillogranular material. Normal maturation of epithelium is prevented by this material, and the cells degenerate and form the visible cysts. Adherence of epithelium to this material is poor, leading to the recurrent erosions. Treatment consists of lubrication and antibiotic prophylaxis during acute episodes and the use of hypertonic ointments at night, which reduces the frequency of spontaneous erosions. Patching may be helpful, but many patients report increased discomfort when patched acutely. Pain relief can be achieved with topical non-steroidal anti-inflammatory drugs (NSAIDs). When surface irregularity reduces vision, the entire epithelium and abnormal basement membrane can be debrided to allow replacement by fresh epithelium. Soft contact lenses worn continuously may provide comfort to patients troubled with frequent erosions. Anterior stromal puncture of the cornea in areas not in the visual axis allows firmer adhesion of the corneal epithelium to the underlying layers, reducing the likelihood of recurrent erosions. Finally, excimer laser phototherapeutic keratectomy (PTK) has been shown to significantly decrease recurrences and improve vision. The occurrence of this disorder in the general population is quite frequent (4) and may represent a degeneration. An autosomal dominant inheritance with incomplete penetrance is suggested, with two studies identifying different point mutations in the TGFBI/BIGH3 gene in a subset of patients with EBMD (5,6). Per the IC3D classification system, most cases of EBMD are sporadic and may be degenerative with a minority of cases being Category 1.

**136.2.2.1 Epithelial Recurrent Erosion Dystrophy (Including Recurrent Hereditary Corneal Erosions) (IC3D Category 3).** This autosomal dominant dystrophy may appear at the age of six months, but is more typically noted around four to six years of age. It is characterized by recurrent corneal erosions in the absence of associated diseases and can be precipitated by minimal trauma, smoke, dust, or exposure to sunlight. The intensity and frequency of the recurrent attacks decline with time and tend to cease by the age of 50. Subepithelial haze or blebs may be seen with the erosions. Additionally, subepithelial opacities can be seen, which vary in appearance from fibrosis to protruding nodules consisting of keloid material based on Congo red staining. The morphological pattern (including an absent Bowman layer, progressive subepithelial fibrosis, abnormal sub-basal corneal nerves) likely reflects the healing response to recurrent epithelial erosions. Medical treatment concentrates on healing the epithelial defect and addressing the loosely adherent epithelium. Cycloplegics, topical antibiotics, lubricating ointments at bedtime, pressure patch, hypertonic saline, and bandage contact lenses can all play a role. The gene and chromosomal locus for this disorder is unknown and it is not genetically linked to any clinically similar corneal dystrophy with autosomal dominant inheritance (3,7–10).

**TABLE 136-1 Classification of Corneal Dystrophies in the International Committee for Classification of Corneal Dystrophies (IC3D)<sup>b</sup>**

Dystrophy	MIM #	Inheritance	Gene Locus	Gene	IC3D Category
Epithelial basement membrane dystrophy	121820	Sporadic or AD	5q31	TGFBI in non-sporadic cases	1 in minority of cases
Epithelial recurrent erosion dystrophy	122400	AD	Unknown	Unknown	3

**FIGURE 136-1** Epithelial Basement Membrane Dystrophy. The gray lines and rings represent reduplications of epithelial basement membrane.

**136.2.2.2 Meesmann Corneal Dystrophy (Including Juvenile Epithelial Corneal Dystrophy and Stocker–Holt Dystrophy) (IC3D Category 1).** Meesmann corneal dystrophy (MECD) consists of multiple, small, round, clear cysts within the corneal epithelium, most prominently in the interpalpebral fissure. Most patients are asymptomatic, but some complain of mild recurrent ocular discomfort, presumably due to rupture of the cysts. Symptoms may occur very early in life but are usually milder than those seen in EBMD. Rarely is vision decreased and corneal sensation may be reduced. Treatment is the same as for EBMD, but aggressive therapy is less often required. Soft contact lens wear can improve comfort and lead to marked attenuation of the corneal cysts. MECD persists throughout life and will recur in regenerated epithelium if the pathologic epithelium is removed (10). The epithelium is disorganized with irregular cell sizes and the formation of cysts within the epithelium that may contain PAS-positive cellular degenerative material. A ‘peculiar substance’ of intracellular fibrogranular material is characteristically seen on electron microscopy of the epithelium. The inclusions in the epithelial cytoplasm have been identified as keratin aggregates, exhibiting irregular clumping of intermediate tonofilaments on electron microscopy. These findings are noted to be similar to other systemic keratin disorders where critical mutations disrupt normal intermediate

filament architecture. The keratins expressed in anterior corneal epithelium are K3 and K12. Both mutations in the keratin 3 (KRT3) gene at 12q13 (11,12) and various mutations in the keratin 12 (KRT12) gene at 17q12 have been described across numerous ethnicities (11,13–17). The mutations in KRT3 and KRT12 appear in the alpha helix rod domain. The numerous KRT12 mutations are in the highly conserved helix initiation and helix termination motifs and the 3 known KRT3 mutations are in the helix initiation motif. Mutations in these motifs can result in structurally fragile corneal epithelial cells that result in the clinical picture seen in this disorder. Autosomal dominant inheritance is well established.

Stocker-Holt corneal dystrophy bears similarities to Meesmann dystrophy in exhibiting a subtle, closely-packed, microcystic epithelium. Findings are more prominent in the interpalpebral zone and cysts may be clear or gray. Patients are usually mildly symptomatic with mild foreign body sensation and reasonable preservation of vision. Histopathology lacks the peculiar substance characteristic of Meesmann dystrophy. A mutation in the KRT12 gene (R19I) has been noted in the original family described (1).

**136.2.2.3 Lisch Epithelial Corneal Dystrophy (IC3D Category 2).** Lisch epithelial corneal dystrophy is characterized by gray bands of epithelial change that appear to be made up of microcysts. The opacities can also display other patterns including whorl-like, flame and feather shaped, radial, and club shaped. Patients complain of decreased vision. Pathological evaluation shows cytoplasmic vacuolization in the corneal epithelium. Treatment consists of corneal epithelial debridement, and there appears to be some benefit from wearing rigid gas-permeable contact lenses. Analysis of the original family indicates inheritance to be X-linked dominant, localizing to Xp22.3 and is distinct from K3 and K12 seen in Meesmann corneal dystrophy (18).

**136.2.2.4 Gelatinous Drop-like Corneal Dystrophy (Familial Subepithelial Corneal Amyloidosis, Subepithelial Amyloidosis, and Primary Familial Corneal Amyloidosis) (IC3D Category 1).** Gelatinous drop-like dystrophy is a form of corneal amyloidosis in which dense droplet-like amyloid deposits accumulate beneath the corneal epithelium during the first decade of life, assuming a ‘mulberry’ shape on the corneal surface (Figure 136-2). The disorder may take various forms, including band keratopathy (19). With time, stromal opacification and fusiform deposits can develop. Superficial vascularization can be seen. This disorder may cause significant visual disability, pain, photophobia, redness, tearing, and foreign body sensation. The deposits and stromal opacities are progressive and difficult to treat. Penetrating keratoplasty is usually unsuccessful because the recipient bed continues to be affected. A novel approach in transplanting

**FIGURE 136-2** Gelatinous Drop-like Dystrophy. Characteristic 'mulberry' appearance seen in the superficial cornea. Lattice corneal dystrophy. Typical ropy lattice lines are evident.

limbal corneal epithelial cells has met with short and intermediate term success (20). This implies that the disorder is at least in part of epithelial origin and is a promising new modality. The disorder is decidedly uncommon in the western hemisphere but is common in Asia. Inheritance is autosomal recessive. Mutations in the TACSTD2 (formerly M1S1) gene at 1p32 cause this disorder; over 20 distinct mutations have been discovered with the Q118X mutation being detected most often (3,10,21,22). Genetic heterogeneity may also be present, as there are reports of individuals with gelatinous drop-like dystrophy who were found to not have mutation in TACSTD2 (10,23).

### 136.2.3 Anterior Membrane Dystrophies

Anterior membrane dystrophies may present with recurrent erosions and epithelial changes but, in addition, demonstrate scarring at the level of Bowman layer – the 'anterior membrane' of the corneal stroma. These disorders have been characterized by their anatomical location. The recent finding of defects in the gene for keratoepithelin, a protein found in cornea, skin, and connective tissue, has led to the closer grouping of the anterior membrane and stromal dystrophies. In the cornea, keratoepithelin is found in greatest concentration in the Bowman layer, the anterior compacted portion of the corneal stroma, as well as in the deeper stroma and Descemet membrane. Ultrastructurally, some is present in the epithelial basement membrane as well (24). The gene for keratoepithelin is known as BIGH3 or TGFBI because transforming growth factor beta can induce its expression. Varying defects in this gene, especially the mutational hotspot codons Arg124 and Arg555, have been associated with some of the anterior membrane dystrophies as well as with granular and most forms of lattice corneal stromal dystrophies (25). Some defects may also be associated with EBMD, as described earlier (Tables 136-2).

**TABLE 136-2** Mutations of the Keratoepithelin Gene Described in Corneal Dystrophies<sup>a</sup>

Dystrophy	Gene Defect
Epithelial basement membrane dystrophy	Leu509Arg, Arg666Ser, Leu559Val <sup>b</sup>
Reis-Bücklers corneal dystrophy	Arg124Leu
Thiel-Behnke corneal dystrophy	Arg555Gln
Lattice corneal dystrophy, type 1	Arg124Cys
Lattice corneal dystrophy – variants	Over 30 exist, please refer to IC3D Classification for full list
Granular corneal dystrophy type 1	Arg555Trp
Granular corneal dystrophy type 2	Arg124His
Granular corneal dystrophy – variants	Val113Ile, Asp123His, Arg124Ser, Arg124Leu + Thr125_Glu-126del

**136.2.3.1 Reis–Bücklers Dystrophy (Including Granular Corneal Dystrophy Type III, Corneal Dystrophy of Bowman Layer Type I-CDBI, Superficial Granular Corneal Dystrophy, Geographic Corneal Dystrophy (Weidle), Atypical Granular Corneal Dystrophy, Anterior Limiting Membrane Dystrophy, Type I (ALMD I)) (IC3D Category 1).** Reis–Bücklers dystrophy (RBCD) is characterized by irregular gray-white reticular changes in the deep corneal epithelium and anterior stroma (Figure 136-3). These changes are evident in the first few years of life and are associated with painful recurrent corneal epithelial erosions, photophobia, and redness of the eyes. The episodes occur every few months for the first one to two decades of life but then become less frequent and often disappear by the age of 20–30 years. As time goes on, however, ring and net-like opacification and epithelial irregularity increase, causing decreased visual acuity. Corneal sensitivity to pain decreases as well. Treatment consists of patching and/or lubrication for the acute erosive episodes and mechanical dissection of the subepithelial and anterior stromal fibrous tissue later in life when visual acuity is significantly decreased. Alternatively, excimer PTK has been successful in reducing the incidence of recurrent erosions and improving visual acuity, but recurrence is common (26). The addition of adjuvant topical

**FIGURE 136-3** Dystrophies Associated with Defects in TGFBI. (A) Type I lattice corneal dystrophy exhibiting thin branching lines. (B) Lattice corneal dystrophy variant (formerly Type III lattice corneal dystrophy). Typical thicker, ropy lattice lines are evident. (C) Reis-Bücklers corneal dystrophy. Epithelial and anterior stromal changes lead to surface irregularity and recurrent erosion. (D) Thiel-Behnke corneal dystrophy. Note the more uniform 'honeycomb' configuration of the superficial opacities (arrow). (E) Granular corneal dystrophy type I. Note the clarity of the cornea between opacities and central location. (F) Granular corneal dystrophy type II. Characteristic snowflakes and discs seen in granular dystrophy with branching, stellate lines of lattice dystrophy.

mitomycin-C may be of benefit in reducing recurrence (27). A potential treatment for young patients may be corneal electrolysis. A group performed this procedure under topical anesthesia on an 11-year-old male with subepithelial opacities. It resulted in significantly improved vision eight months later, but further follow-up was not reported (28). Occasionally, scarring will be sufficient to warrant penetrating keratoplasty, although recurrence has been seen in some grafts. Pathological examination reveals irregularity of the epithelium with focal absence of epithelial basement membrane and disruption of basal epithelial cells and their attachments. Bowman layer, the anterior compacted portion of the corneal stroma, is diffusely disrupted and replaced with fibrous connective tissue with deposits staining for Masson trichrome that

projects into the subepithelial zone. Accumulation of keratoepithelin products have been shown between the epithelium and Bowman layer (29,30), and they are seen as characteristic rod-shaped bodies on electron microscopy that are immunopositive for keratoepithelin (24). This disorder is autosomal dominant in inheritance and caused by an Arg124Leu mutation in the TGFBI gene.

There have been reports suggesting that another TGFBI mutation, Gly623Asp, is causative of RBCD based on clinical examination, but histopathological exam was either not conducted for confirmation (31,32) or was inconsistent with the lack of Masson trichome staining (33). Other patients reported to have the Gly623Asp mutation had clinical phenotypes that were not similar to RBCD (34,35) and both

histopathological examination and electron microscopy on one of those patients was not compatible with RBCD (35), which suggest that this mutation could be causing a novel corneal dystrophy. Currently, the IC3D classifies this mutation as variant lattice corneal dystrophy (3). Another suspected mutation, a F540 deletion, for RBCD also lacks histopathological confirmation and is classified as variant lattice corneal dystrophy (3,10). Another study of a family with a clinical picture of RBCD showed an Arg124Cys mutation (which is normally associated with lattice corneal dystrophy) but also lacked histopathological confirmation (36).

**136.2.3.2 Thiel–Behnke Corneal Dystrophy (Including Corneal Dystrophy of Bowman Layer Type II-CDBII, Honeycomb-shaped Corneal Dystrophy, Anterior Limiting Membrane Dystrophy, Type II, Curly Fibers Corneal Dystrophy, Waardenburg–Jonkers Corneal Dystrophy) (IC3D Category 1, Potential Variant Is Category 2).** Thiel and Behnke described a similar clinical disorder in 1967 with honeycomb-like changes beneath the corneal epithelium (Figure 136-3), which is later in onset than Reis–Bücklers and has normal corneal sensation. The peripheral cornea is usually uninvolved. Vision gradually becomes impaired. Treatment is similar to Reis–Bücklers with good success (37). Thiel–Behnke corneal dystrophy (TBCD) is also known as curly fiber dystrophy, because characteristic electron dense ‘curly filaments’ replace Bowman layer. Clinical differentiation of RBCD from Thiel–Behnke is often difficult, making histological confirmation critical in assigning mutational defects. The curly fibers are immunopositive for keratoepithelin and pathognomonic in distinguishing this disorder from RBCD. While not considered to be definitive from a diagnostic standpoint, confocal microscopy has been used to distinguish TBCD from RBCD (38) and can be a useful tool when tissue is not available for histopathological analysis. TBCD has been mapped to TGFBI and it is thought that Arg555Gln may be specific for this disorder and that the two disorders are genotypically distinct (25,39,40). Some have diagnosed TBCD by clinical phenotype and the Arg555Gln mutation alone without obtaining ultrastructural information needed for confirmation. Genetic heterogeneity may exist, as some families with Thiel–Behnke have been linked to a defect at 10q24; the gene is unknown.

**136.2.3.3 Grayson–Wilbrandt Corneal Dystrophy (IC3D Category 4).** In 1966, Grayson and Wilbrandt described an autosomal dominant disorder in a single family that was similar to Reis–Bücklers dystrophy, with slightly later onset, less epithelial irregularity, less severe recurrent erosions and normal corneal sensation. Histopathologically, there is a homogenous eosin-staining material in between the epithelium and the Bowman layer. It stains with Periodic acid-Schiff, but not Alcian blue or Masson trichrome.

## 136.2.4 Band Keratopathy

Although quite rare, patients with primary band keratopathy have been reported. In its juvenile form, calcification presents early in life with whitish opacification in the interpalpebral region of the cornea, beginning at the limbus and progressing centrally. Sufficient central progression may reduce vision and fragmentation of the calcium may cause epithelial disruption and discomfort. In time, secondary corneal scarring and vascularization may occur. The adult form presents in a similar fashion late in life. Treatment consists of debridement and chelation of the calcium, with a combination of mechanical scraping and soaking with disodium EDTA. Excimer PTK is also an alternative as it is in most anterior stromal dystrophies. Differential diagnosis includes the numerous secondary causes of band keratopathy, including chronic ocular disease (e.g., uveitis, interstitial keratitis, Norrie disease), trauma, hypercalcemia, hypophosphatasia, and renal failure. In all forms of band keratopathy, calcium is deposited in Bowman layer of the cornea. Predisposition for the central cornea may relate to pH changes and evaporation from the tear film in the interpalpebral zone. Primary band keratopathy appears to be autosomal recessive in inheritance.

## 136.2.5 Stromal Dystrophies

Stromal dystrophies are highlighted by the accumulation of opaque substances in the corneal stroma, either within the keratocytes or between the stromal collagen fibers.

**136.2.5.1 Lattice Corneal Dystrophy.** Lattice dystrophy (LCD) has been the term used to describe a number of entities in which linear accumulations of amyloid are found in the corneal stroma. Types I, II, III, IIIA, and IV have previously been described. The IC3D classification system has reorganized lattice dystrophy as type 1, LCD variants (which includes former types III, IIIA, and IV), and type 2 (3).

**136.2.5.1.1 Lattice Corneal Dystrophy Type I (Including Classic LCD, LCD Type I, Biber–Haab–Dimmer) (IC3D Category 1).** In lattice dystrophy (LCD) type I refractile short rod-like lines, dense branchingropy lines, and smaller dot-like opacities are present in the corneal stroma at all levels (Figure 136-3). The corneal periphery is usually clear, and although a central haze may be present anteriorly in the stroma, most of the stroma between the opacities is clear. Anterior opacities may extend beneath the epithelium and lead to epithelial irregularity and corneal erosion. The corneal opacities become evident in the first and second decades of life and progress in extent and density. The earliest symptoms are usually due to recurrent epithelial erosions and blurring of vision caused by epithelial irregularity. As the central haze progresses in the fourth and fifth decades of life, visual acuity may decline further. Early therapy is directed to the recurrent erosions, whereas soft

contact lenses may improve acuity reduced by corneal surface irregularity. With more advanced opacification, penetrating keratoplasty successfully restores vision, although opacification may ultimately recur in the graft. Excimer laser ablation of superficial opacities may help some patients defer the need for keratoplasty (41). Moderate variability in degree of involvement exists, and unilateral cases have been reported (42,43). The major differential confusion comes from granular and macular dystrophies, which are discussed later. Histopathologically, amyloid deposits are demonstrated in the stroma in fusiform clumps that are most concentrated anteriorly. Normal stromal collagen lies adjacent to it. Inheritance of lattice dystrophy type I is autosomal dominant. The majority of reported cases indicate a R124C mutation (25,44) resulting in an accumulation of the N-terminal portion of the TGFBI (30). Phenotypic variation with the R124C mutation has been seen, with one group having reported five patients with features of both gelatinous drop-like dystrophy and LCD type I (45). Two studies reported patients who had clinical and histopathological features resembling Avellino corneal dystrophy (46,47). As mentioned previously, a group reported a family with a clinical picture of RBCD without histopathological confirmation (36). It is not yet known how this phenotypic diversity with the same mutation occurs, but one can speculate that other processes are involved, such as environmental influences or other corneal-specific genes that have not yet been elucidated.

**136.2.5.1.2 Lattice Corneal Dystrophy Variants.** Over 30 variants of LCD have been discovered. While there is phenotypic variability, almost all of these mutations lie in the Fas-1 domain 4 of TGFBI (the Arg-124Cys mutation is in domain 1). The mutations in this domain include conserved sequences and may affect protein structure leading to phenotypic abnormalities (48). This includes mutations outside of the 124 codon that result in LCD, type I such as Leu518Pro, Leu569Arg, Val539Asp, Val505Asp, and Ile522Asn (49–53).

In 1987, Hida et al. described the first cases of lattice dystrophy type III, which is now grouped under LCD variants. It is not associated with corneal erosions and has onset after age 40. The corneal lines are much thicker than in LCD type I (Figure 136-3). Unilateral cases have been reported. This disorder appears to be autosomal recessive. The localization of the gene is not conclusive, but an L527R mutation in TGFBI has been seen in cases of lattice dystrophy with histological features similar to LCD type III (54,55). One group reported a homozygous Val624Met mutation in 2 brothers, one of whom had a unilateral presentation similar to LCD type III and the other mild bilateral stromal opacities. The proband's daughter was heterozygous for the mutation and had no reported ophthalmic abnormalities (56).

Patients with findings similar to lattice type III, but with recurrent corneal erosion and dominant transmission, have been described as type IIIA, which is also now

classified under LCD variants. In Japan, a Pro501Thr mutation in TGFBI has been found in this disorder (57). Clinical LCD type IIIA has also been described with an Ala546Thr mutation (58), a deletion/frameshift mutation at Val627, Asn622Lys mutation (25) and a Phe-540Ser mutation (59).

Also classified under LCD variants is type IV lattice dystrophy. It is characterized by late onset of deep stromal opacities without corneal erosions and has been described with a Leu527Arg mutation (49,60) that has been suggested to be a founder mutation in a single Japanese ancestor (61). An atypical form of this variant has also been mapped to Asn544Ser (62), Val631Asp (25), and Gly594Val (51). One group reports a patient with a clinical picture of LCD type 4 as having an Arg496Trp mutation. This mutation is unique in comparison to the others by being located in the third Fas domain instead of the fourth (63).

LCD variants also include phenotypes with features of both type I and type IIIA. Schmitt-Bernard et al. (2000) have described such an entity, with late onset, asymmetric progression with lattice lines thicker than type 1, but thinner than type IIIA (64). This was associated with an Asn-Val-Pro629-30 insertional mutation (65). A similar intermediate dystrophy has been mapped to an H626R mutation in TGFBI in both Caucasian (40) and Asian families (66). Other mutations that result in a similar clinical picture include Asn622His (24), Thr538Arg, Leu518Arg, and His626Pro (25). As mentioned previously, Gly623Asp and a F540 deletion had been thought to be a cause of RBCD, but it is currently viewed as a LCD variant within the IC3D based on clinical diagnoses (25).

Varied phenotypes have been reported with the Ala546Asp mutation. Eifrig et al. reported on a family that had a clinical picture of polymorphic stromal opacities without a distinct lattice pattern and no corneal erosions. On histological analysis, amyloid was seen within the deep stroma. The authors designated this disorder as polymorphic corneal amyloidosis (67). Other studies have shown that such a designation may be too specific. Correa-Gomez et al. reported on another family with the same mutation and, while there were similarities in the morphology of the corneal opacities and amyloid deposition, there was a more distinct lattice pattern on clinical exam (68). Two groups reported families that had an Ala546Asp mutation along with a Pro551Gln mutation. One family was recognized to have a phenotypic LCD type I picture (69) while the other family's affected members had lattice lines with polymorphic stromal opacities and amyloid deposition (70). While the Ala546Asp mutation can result in different clinical findings, the P551Q mutation would also appear to have a role in modifying phenotype. Genetic heterogeneity with polymorphic corneal amyloidosis is also suggested by reports of a case with a F547S mutation (71) and cases without a pathogenic TGFBI mutation (72).

**136.2.5.1.3 Lattice Corneal Dystrophy Type II, Gelsolin Type (Familial Amyloid Polyneuropathy Type IV – Finnish Type, Meretoja Syndrome, Amyloidosis V) (IC3D Category 1).** Another form of lattice corneal change (LCD type II) has been noted in patients with familial amyloid polyneuropathy type IV (Finnish type, Meretoja syndrome). The opacities occur later in life, do not leave a clear periphery to the cornea, and there are fewer lattice lines and markedly fewer dot-like opacities. The lattice lines are more radially oriented compared to LCD type I. The central cornea is less severely involved, so that visual disturbance is less common and occurs later (in the sixth decade). Corneal sensitivity is decreased. After the age of 40, facial paresis and dermatochalasis are exceedingly frequent. Histopathology in these patients demonstrates amyloid, as does lattice dystrophy, with occasional suggestion of perineural distribution. The amyloid deposits are seen in the cornea, lacrimal gland, and scleral, choroidal, and adnexal blood vessels. A mutation in the gelsolin gene (GSN; 9q34) had been demonstrated in these families and a mutated 71 amino acid fragment of gelsolin makes up the amyloid seen in this disorder. A G654A missense mutation (resulting in Asp187Asn) has been found in Finnish, Portuguese, American, British, Japanese, Iranian, Spanish, and German families (73–78), while a G654T mutation (resulting in Asp187Tyr) is seen in Danish, Czech, and French families with LCD type 2 (79–81). The resulting accumulation of abnormal amyloidogenic gelsolin is the same with both mutations (74,80).

#### **136.2.5.2 Granular Corneal Dystrophy.**

**136.2.5.2.1 Granular Corneal Dystrophy, Type I (Including Corneal Dystrophy Groenouw Type I) (IC3D Category 1).** Granular corneal dystrophy Type I (GCD1) is characterized by very discrete white opacities in the central anterior corneal stroma. The opacities are moderately large (0.1–0.4 mm in diameter) and may take several shapes, although most commonly they are crumb-like (Figure 136-3). The corneal periphery is spared, and the corneal stroma is generally clear between opacities but may become slightly hazy as opacities coalesce. The opacities occur in the first decade of life but are mostly asymptomatic until later life, when there may be reduction in visual acuity. Corneal erosions are not common. Most patients require no treatment, but those with opacification sufficient to cause visual disability do well with corneal transplantation. Grafts usually do not have recurrence for at least 30 months, but opacities can be seen as soon as within a year at the graft–host interface or in the superficial donor tissue. Corneal electrolysis has been used to remove recurrent deposits after keratoplasty, and while the deposits recur within two to three years, this could delay the necessity of another transplant (82). Debridement or laser ablation (PTK) of the corneal epithelium in patients with early superficial opacities and visual symptoms or corneal erosions has been reported to improve symptoms (83,84). Recurrence

has been reported after PTK and in grafts (85). The use of soft contact lenses (86) and, because of its presumed epithelial origin, limbal stem cell transplants have been advocated (87). The most important clinical differential diagnosis is between this disorder and macular corneal dystrophy, which has a similar corneal appearance but less discrete opacities and markedly greater stromal haze that extends to the corneal periphery. Histological corneal specimens demonstrate aggregation of nodular hyaline material that stains with Masson trichrome throughout the stroma, but is more prominent anteriorly. The material is phospholipid and noncollagenous protein, which closely mimics a portion of TGFBI. Rod-shaped bodies that appear similar to those seen in RBCD are seen on transmission electron microscopy. Inheritance is autosomal dominant. A defect in TGFBI, Arg555Trp, is the most common mutation reported in GCD type I (88,89), but one case of a de novo mutation has been reported (90). Phenotypic variation is possible, with Arg555Trp, as shown with two patients displaying a vortex pattern in the granular deposits (91). Homozygous cases are more severe in appearance and disability and also respond more poorly to therapy (92).

#### **136.2.5.2.2 Granular Corneal Dystrophy, Type II (Including Avellino Corneal Dystrophy, Combined Granular-Lattice Corneal Dystrophy) (IC3D Category 1).**

A variant of granular dystrophy with lattice-like amyloid deposits in addition to granular opacities has been described, and is now referred to as granular corneal dystrophy, type II (GCD2). The corneal findings include thin linear opacities similar to LCD type I, but are less prominent. Granular opacities may be more variable in appearance than GCD type I, described as snowflake or stellate. Onset is later than GCD1 and homozygous genotype results in a more severe form of the disease. There has been one report of a Chinese family with reduced penetrance of the GCD2 phenotype, which would suggest that environmental and other genetic factors may have an influence in the disease process (93). Histologically, there are hyaline and amyloid deposits that stain with Masson trichrome and Congo red respectively. Homozygotes have more severe histological findings. As in GCD1, penetrating keratoplasty can be performed, but recurrence can occur. One group published a study in which granular deposits were absent in areas of corneal neovascularization and suggested that identification of the responsible vascular factors might provide another treatment option (94). Refractive surgery is contraindicated in GCD2, since it can become exacerbated with increased corneal opacification (95–100). The first described patients originated from the Italian province of Avellino, which led to the term ‘Avellino dystrophy’. It is also known as combined granular-lattice dystrophy or R124H mutant TGFBI dystrophy. The majority of described pedigrees are, interestingly, from Japan, where it is the most common granular corneal dystrophy (57). GCD2 is also prevalent in Korea, where it is estimated

that 11.5 per 10,000 persons are affected (101). A mutation in the keratoepithelin gene, Arg124His, is virtually always found in this disorder (57,102). Similar to GCD type I, the cornea shows accumulation of TGFBI components, indicating the central role of the R124H mutation (30,103).

**136.2.5.2.3 Granular Dystrophy Type III and Granular Dystrophy Variants.** Granular dystrophy type III is superficial granular or Reis–Bücklers dystrophy, which is described above with the anterior membrane dystrophies. Granular corneal dystrophies have been described with clinical characteristics intermediate between type 1 and type III GCD, as well as exams not typical of either form. One variant has 2 mutations, R124L and a deletion of Thr125 and Glu126 (104), while another has a D123H mutation (89,105). These may represent an additional type of GCD or an intermediate variant. Another variant has a mutation at R124S and appears to be very similar to GCD1 with the exception of having a later onset (25,106). H626R, a mutation that has been classified as a LCD variant in the IC3D, was also reported in a patient with a clinical picture of GCD1 (107). More recently, two sisters in their second decade with a Val-113Ile mutation were reported to have a variant of GCD with anterior and midstromal granular lesions that had more peripheral than central involvement (108).

**136.2.5.3 Macular Corneal Dystrophy (Including Groenouw Corneal Dystrophy Type II, Fehr Spotted Dystrophy) (IC3D Category 1).** Macular corneal dystrophy differs from the preceding two classical corneal dystrophies in that it is autosomal recessive. Corneal opacification consists of diffuse stromal haze as well as focal gray-to-white opacities (Figure 136-4). Initially, central anterior opacities occur in the first decade of life and become deeper and more diffuse with significant ground-glass haze in the stroma between opacities. By the third or fourth decade, the opacities have extended into the deeper stroma and to the corneal endothelium with development of irregular guttae in Descemet membrane. Characteristically, involvement extends to the limbus, and the stroma between opacities is somewhat hazy, which allows this disorder to be distinguished from granular dystrophy. The corneal stroma is usually thinner, which seems to be explained by decreased interfibrillar spacing between collagen fibrils in diseased corneas compared to normal corneas (10). Photophobia, decreased corneal sensation, and recurrent erosions can occur. Visual acuity is often significantly reduced by the third decade of life, prompting keratoplasty. Success with surgery is high, but opacification may recur in grafts with varying degrees of visual impairment. While good results from lamellar keratoplasty have been reported (109), penetrating keratoplasty is the preferred choice when the pathology is not restricted to solely the anterior or posterior lamellae. Laser ablation may be helpful in early symptomatic cases with superficial involvement. Histopathologically, the Bowman layer, the corneal

**FIGURE 136-4** Macular Corneal Dystrophy. Diffuse clouding is present between the denser opacities.

stroma, Descemet membrane, and the corneal endothelium show excess accumulation of mucopolysaccharide (glycosaminoglycans) within lysosomes, Golgi vesicles, and endoplasmic reticulum as well as extracellularly between collagen fibrils (110). The accumulations are positive for stains for glycosaminoglycans, such as Alcian blue, colloidal iron, and periodic acid-Schiff. On electron microscopy, keratocytes and corneal endothelium show intracytoplasmic accumulations along with vacuoles and lamellar bodies. The extracellular matrix shows fibrillo-granular material that stains for glycosaminoglycans.

The mucopolysaccharide that accumulates is non-sulfated keratan sulfate related to a defect in a specific sulfotransferase, GlyNAc6ST (111). Studies of corneal explants suggest altered synthesis of keratan sulfate as well as other glycosaminoglycans. Furthermore, corneal explants from some patients with macular dystrophy have synthesized normal keratan sulfate proteoglycan but shortened dermatan sulfate chains. Keratan sulfate is normally found only in the cornea and cartilage. Cartilage from some macular dystrophy patients lacks normal keratan sulfate. Macular corneal dystrophy has been subdivided by the presence or absence of antigenic keratan sulfate in serum and in the cornea. Type I has none detectable in either the serum or cornea, type IA has antigenic keratan sulfate detectable in the cornea but not the serum, and type II has it detectable in both the serum and cornea. These immunophenotypes cannot be

differentiated on a clinical level and do not appear to have any clinical significance. The genes for types I and II were localized to 16q22 and have been fine mapped to a region containing a sulfotransferase gene, CHST6 (112). Since its description, a myriad of mutations have been identified in the CHST6 gene in macular dystrophy, indicating mutational heterogeneity leading to a common protein dysfunction (3,113–119). One case of macular corneal dystrophy could not be explained by CHST6 mutations, deletions or insertions in the upstream region, or by splice site mutations. This could indicate the existence of genetic heterogeneity or abnormalities in regulatory elements (120).

**136.2.5.4 Schnyder Corneal Dystrophy (Including Schnyder Crystalline Corneal Dystrophy, Central Stromal Crystalline Corneal Dystrophy, Schnyder Crystalline Dystrophy Sine Crystals, Hereditary Crystalline Stromal Dystrophy of Schnyder, Crystalline Stromal Dystrophy, Corneal Crystalline Dystrophy of Schnyder, Schnyder Corneal Crystalline Dystrophy) (IC3D Category 1).** In Schnyder corneal dystrophy (SCD), various patterns of lipid deposition are seen in the corneal stroma. Classically, central fine stromal crystals appear in the first year of life and progress. The crystals are also seen in Bowman layer. Eventually, corneal arcus and central stromal haze appear in the third or fourth decade of life. Fine crystals are deposited in a ring surrounding the central portion of the cornea, with less dense crystals and gray-white whorl-like lesions centrally. A dense lipid arcus at the corneal periphery and a girdle of anterior denser lipid at the nasal and temporal limbus are usually present. Only about half of the patients have the classic crystals with the remainder having non-crystalline lipid haze. Commonly, there is only mild disturbance of vision (121), with scotopic vision remaining good and photopic vision decreased. The decrease in photopic vision usually leads to a need for corneal transplantation sometime after the fifth decade (122). Recurrence has been reported but is infrequent and mild (123). Laser superficial keratectomy has also shown promise in improving vision (124,125). Two systemic findings have been associated with this disorder frequently enough to raise the question as to whether this is a true dystrophy or a systemic disorder. Genu valgum and other joint abnormalities have frequently been noted, but not in all families. Hyperlipemia with elevation of serum cholesterol and triglycerides has also been noted often, but families have been reported in which some members have both corneal changes and hyperlipemia, some only corneal changes and others only hyperlipemia. Previous work had failed to find a correlation between systemic disturbances in lipid metabolism and Schnyder dystrophy, suggesting that the metabolic abnormality is localized in the cornea. Others have found abnormal storage of lipid in skin fibroblasts in a family with this disorder. Histological examination of corneal specimens demonstrates the presence of cholesterol crystals, neutral

fats, and triglycerides in the corneal stroma. Esterified and unesterified cholesterol can be seen in basal epithelial cells, Bowman layer, stroma, and, rarely, endothelium. Positive staining is observed with lipid stains such as oil red O and Sudan black. On immunohistochemistry, apolipoprotein components of HDL can be detected. Crystalline dystrophy is an autosomal dominant disorder. The locus of the responsible gene, UBIAD1, is at 1p36, and multiple mutations can cause SCD (126–130). Recent work that has investigated protein homology, and molecular modeling suggests that mutations in UBIAD1 can cause a loss of function mutation in a mitochondrial prenyltransferase that affects cholesterol metabolism in an unknown manner (131).

A previous study (132) had proposed a novel dystrophy, central discoid corneal dystrophy (CDCD), based on examination of a family with clinical findings similar to SCD. Genetic analysis revealed a novel mutation in UBIAD1, suggesting that CDCD is a variant of a SCD (133).

**136.2.5.5 Congenital Stromal Corneal Dystrophy (Including Congenital Hereditary Stromal Dystrophy, Congenital Stromal Dystrophy of the Cornea) (IC3D Category 1).** Congenital stromal corneal dystrophy (CSCD) is an autosomal dominant disorder that begins at or shortly after birth and exhibits corneal haze with flaky opacities throughout the stroma in the entire cornea. These opacities become more numerous with time. Descemet membrane and the endothelium appear normal. Strabismus and nystagmus can be seen in affected patients. Penetrating keratoplasty may be needed and has resulted with clear grafts or minimal recurrence. It has been described in multiple families in Belgium, France, Norway, and Germany and is characterized on electron microscopy with unusually small, tightly packed collagen fibrils aligned in a random pattern (134). CSCD is caused by truncating mutations in the decorin (DCN) gene at 12q21 (135,136). Decorin is thought to play a regulatory role in collagen fibrillogenesis and matrix assembly. The stromal opacities seen on clinical exam are at least partially composed of accumulated truncated DCN protein (137).

**136.2.5.6 Central Cloudy Dystrophy of Francois (Including Posterior Crocodile Shagreen) (IC3D Category 4).** In central cloudy dystrophy cloud-like areas of haze occur centrally in the deep corneal stroma. Polygonal patches are separated by clear areas that form a pattern similar to the scales of a crocodile's skin (Figure 136-5), hence another of its descriptive names. It is virtually indistinguishable from posterior crocodile shagreen, which is a corneal degeneration and is not familial. This is usually seen as an incidental finding on routine examination at any age, although it is more common in later years. It produces no symptoms and requires no therapy. Histopathology of a single case showed extracellular mucopolysaccharide and lipid in the corneal stroma. Inheritance has been reported to be autosomal dominant

**FIGURE 136-5** Central Cloudy Dystrophy. The slit beam highlights the crocodile-skin opacities.

in a few families, but genotyping was not available at the time of these studies to confirm this. It is possible that these cases were instead posterior crocodile shagreen (3).

#### **136.2.5.7 Fleck Dystrophy (Including Speckled Dystrophy, Francois–Neetens Dystrophy) (IC3D Category 1).**

Fleck dystrophy is characterized by congenital, non-progressive fine opacities throughout the corneal stroma. The opacities are tiny discs or rings with clear centers. Patients are almost always asymptomatic and require no treatment, although photophobia and decreased corneal sensitivity have been reported. Asymmetry can occur and may occasionally be striking. Laser-assisted in situ keratomileusis (LASIK) does not appear to result in worsened vision based on a case report (138). A differential distinction must be made between this disorder and granular dystrophy, but the finer size and more diffuse distribution of opacities in fleck dystrophy usually create little difficulty with diagnosis. Patients with both fleck opacities and central cloudy dystrophy have been described, leading to the suggestion that these entities represent variations in expression of the same genetic defect. Histopathologically, most keratocytes are normal, whereas affected keratocytes demonstrate membrane-bound vacuoles containing acid mucopolysaccharide and lipid. The metabolic source of this accumulation is unknown. Inheritance is autosomal dominant and is due to mutations at PIP5K3, a phosphoinositide 3-kinase, at 2q35 (139,140).

**136.2.5.8 Posterior Amorphous Corneal Dystrophy (Including Posterior Amorphous Stromal Dystrophy) (IC3D Category 3).** Posterior amorphous corneal dystrophy is autosomal dominant and is characterized by

a gray sheet-like opacity in deep stroma near Descemet membrane. Transparent stromal breaks can be seen within the opacification. The lesions can be peripheral or centroperipheral, with the latter extending to the limbus and exhibiting corneal thinning with a flattened corneal curvature. Visual acuity is not greatly affected and usually requires no treatment. If necessary, a penetrating keratoplasty can be performed for severe visual impairment. Histologically, an irregular stromal architecture with attenuated corneal endothelium has been noted. On electron microscopy, abnormally oriented collagen fibers can be noted and some collagen fibers may interrupt Descemet membrane. This disorder has been observed as soon as 16 weeks after birth and may be a developmental disorder. Non-corneal findings are also present, including iris abnormalities such as corectopia, iridocorneal adhesions, papillary remnants, and pseudopolycoria. The responsible gene is currently unknown, but Aldave et al. have recently identified 12q21.33 as a locus. They were unable to detect mutations in candidate genes in the locus (KERA, LUM, DCN, EPYC) (141).

#### **136.2.5.9 Pre-descemet Corneal Dystrophy (IC3D Category 4).**

This is a disorder that is not well defined or associated with a definitive pattern of inheritance. It is unknown whether it is a hereditary or degenerative disorder. Onset is usually after 30 years, but the condition has been found in young children. Several subgroups exist. In one form gray opacities occur in the deep stroma just anterior to Descemet membrane with variable morphology, size, and distribution across the cornea. The punctiform and polychromatic subtype has more uniform and polychromatic changes. Similar lesions have been seen in association with systemic and other ocular disorders, such as X-linked and recessive ichthyosis, Fuchs endothelial corneal dystrophy (142,143), keratoconus, and pseudoxanthoma elasticum.

#### **136.2.5.10 Bietti Crystalline Corneoretinal Dystrophy and Other Stromal Dystrophies.**

Although it is not classified as a corneal dystrophy in the IC3D, we will briefly discuss Bietti crystalline corneoretinal dystrophy and its characteristic findings. In this disorder, very subtle fine crystals are seen in the cornea located in the anterior stroma. Also known as Bietti marginal corneal dystrophy, the lesions are marginal or paralimbal, as implied by the name. The disease is primarily characterized by a retinal degeneration with vascular sclerosis, night blindness and progressive visual field constriction. Crystal-like deposits have been reported on the anterior and posterior lens capsule of a patient with this disorder (144). Histopathology shows crystals and cytoplasmic inclusions in both corneal and conjunctival fibroblasts. The disorder has been mapped to chromosome 4 (4q35) (145) and, subsequently, the CYP4V2 gene (146) with numerous mutations reported (147–149). The function of the gene product is unknown, but the gene shares homology with genes involved in lipid metabolism, long suspected to be the defect in Bietti's corneal dystrophy (146).

**FIGURE 136-6** Fuchs Dystrophy. Epithelial and stromal edema as well as wrinkling of the posterior cornea are most prominent in the central cornea.

Several other disorders that cause opacities of various shapes and sizes in the deep stroma have been described. These include cornea farinata, deep filiform dystrophy, and polymorphic stromal dystrophy. Because these have not been well demonstrated to be inherited and may represent degenerative changes, the term *dystrophy* may not be warranted in these disorders. Deep filiform dystrophy and cornea farinata have been described in association with keratoconus and X-linked ichthyosis.

### 136.2.6 Endothelial Dystrophies

Endothelial dystrophies involve the corneal endothelium, which produces the dense Descemet membrane as its basement membrane. The endothelial cells actively maintain the cornea in a state of normal hydration. When endothelial dysfunction occurs, the corneal stroma and epithelium become overly hydrated, causing corneal edema, clouding, and decreased vision. Thus, this group of disorders is a frequent cause of visual disability.

**136.2.6.1 Fuchs Endothelial Corneal Dystrophy (Including Endothelial Corneal Dystrophy, Cornea Guttata, Endoepithelial Corneal Dystrophy) (IC3D Category 1 [Early-onset], Category 2 [Genetic Loci Known, Gene Unknown], Category 3 [No Known Inheritance]).** Fuchs dystrophy (FECD) initially is asymptomatic; fine guttate excrescences in Descemet membrane, often with overlying fine pigment dusting, are present on biomicroscopic examination. These excrescences are called corneal guttae. Later, stromal edema and clouding develop with wrinkling and thickening of Descemet membrane. At the same time, the corneal epithelium becomes edematous, initially with fine epithelial intracellular edema, then intercellular cyst formation, and ultimately with bleb-like separation of the epithelium (termed ‘bullous keratopathy’). All findings are most prominent centrally, but with prolonged disease the entire cornea eventually becomes edematous (Figure 136-6). The disorder is bilateral but often asymmetric, and females are more frequently affected

than males. Although corneal guttae may be noted on examination in asymptomatic patients in their thirties, symptomatic disease does not usually occur until the fifth or sixth decades. In certain families, patients may become symptomatic in their teens with smaller guttae. The first symptom is often hazy vision on arising in the morning, which abates as fluid evaporates from the cornea during the waking hours. As endothelial dysfunction increases, corneal edema becomes more persistent; eventually, vision remains blurred constantly. With the development of bullous epithelial edema, bullae may rupture and cause episodes of severe pain. With prolonged disease, subepithelial fibrosis, stromal vascularization, and fibrous thickening of Descemet membrane occurs. Treatment in the early stages consists of the use of hypertonic solutions administered as topical ocular drops to aid corneal dehydration. Painful bullae can be treated with the use of continuously worn soft contact lenses for palliation. Ultimate treatment requires corneal transplantation, more often a posterior lamellar transplant such as Descemet stripping automated endothelial keratoplasty (DSAEK), to restore both vision and comfort. Differential distinction must be made between Fuchs dystrophy and secondary causes of corneal endothelial dysfunction, including inflammatory diseases and trauma. Pathological examination shows decreased endothelial cell density; the remaining endothelial cells produce excess collagen posterior to Descemet membrane and become less effective as fluid barriers and pumps to dehydrate the corneal stroma. As noted previously, excess hydration of the corneal stroma and epithelium ensues. Electron microscopy reveals multiple layers of basement membrane-like material on the posterior part of Descemet membrane and immunohistochemistry has shown fibrinogen/fibrin in the posterior collagenous layer.

The basic pathogenetic mechanism of the cellular loss and dysfunction is unknown, but is likely multifactorial. Studies of Fuchs’ patients have noted an irregularity in the regulation of apoptosis (150,151). One study investigated the aqueous humor proteome in patients with

FECD and found altered levels of a few proteins involved in cell protection and survival, which could influence endothelial cell health (152). Additionally, one group discovered activation in the unfolded protein response in the corneal endothelium of FECD patients, suggesting a pathogenesis for cellular loss. This pathway manages improperly folded proteins and apoptosis occurs if the cell is overwhelmed with an excess of these proteins (153). Although most patients present as sporadic cases, described families strongly suggest a dominant pattern of inheritance, although there is a significant predominance of affected females. The prevalence of this disorder is lower in Asia than in North America. A patient with mitochondrial DNA missense mutation and multiple nonocular anomalies was also found to have Fuchs dystrophy, which may be coincidental or could implicate a role for mitochondrial DNA. A missense substitution, Gln455Lys, in the COL8A2 gene on chromosome 1, has been described in both Fuchs endothelial corneal dystrophy and posterior polymorphous dystrophy in a three-generation family with early Fuchs manifestations. It has also been seen in sporadic cases (154,155). Another COL8A2 mutation in early onset Fuchs, Leu450Trp, has been discovered in two families (156,157). This gene is involved in collagen VIII synthesis, which has been identified in Descemet membrane. Other studies of familial FECD as well as sporadic cases have not found mutations in COL8A2 (158,159). Genetic heterogeneity appears to exist, as late-onset FECD has been mapped to four loci on chromosomes 13 (FCD1) (160), 18 (FCD2) (161), 5 (FCD3) (162), 9 (FCD4) (163), and the SLC4A11 gene, which is also causative for congenital hereditary endothelial dystrophy type 2 (CHED 2) (164,165). The involvement of mutations in genes that cause other dystrophies (such as CHED2 or posterior polymorphous corneal dystrophy) could suggest that the endothelial dystrophies are on a spectrum of clinical disorders with genetic overlap.

**136.2.6.2 Congenital Hereditary Endothelial Dystrophy (Including Maumenee Syndrome) (IC3D Category 2 [CHED 1], Category 1 [CHED 2]).** Congenital hereditary endothelial dystrophy (CHED) refers to two entities with different patterns of inheritance and clinical courses. Ultimately, both forms have dense corneal opacification due to marked stromal edema, with stromal thickness increased to two or three times normal without vascularization. Fine epithelial edema without bullae is present. When visible, the region of Descemet membrane is thickened, but no guttate changes are present. The autosomal recessive form (type 2) presents with bilateral corneal clouding at birth or in the neonatal period. Symptoms of discomfort are absent and corneal clouding progresses very little with age. Nystagmus is often present. CHED 2 can be associated with hearing loss (Harboyan syndrome) (166). In the dominant form (type 1), photophobia and tearing are noted very early in life and biomicroscopic examination reveals corneal

stromal and epithelial edema, which progresses in the first to second year of life to milky corneal opacification. Nystagmus is uncommon. In both disorders, visual acuity is markedly reduced, but some useful vision may be retained. There are no consistent systemic abnormalities. On histopathology in both types, the number of endothelial cells is reduced and Descemet membrane can appear thick and laminated. Similar to posterior polymorphous corneal dystrophy (PPCD), the endothelial cells in CHED 1 express cytokeratin that is unlike normal endothelium (167). Corneal grafting has been carried out in some patients. The results were disappointing in older studies but more recently have been reported as yielding significant improvement in vision, even when grafting is carried out in adulthood. The use of topical hypertonic agents may provide some improvement in symptoms and acuity. Differentiation must be made between this disorder and others that present with corneal opacification early in life. Congenital glaucoma must be ruled out by the demonstration of normal intraocular pressure, lack of optic nerve cupping (if the nerve head can be seen), and lack of buphthalmic enlargement of the corneal diameter. Metabolic disorders can be ruled out by systemic evaluation and biochemical analysis. Birth trauma with rupture of Descemet membrane is unilateral, and the edema clears over time. Intrauterine inflammation is usually associated with other ocular abnormalities in addition to corneal edema. Posterior polymorphous dystrophy may present confusion and is discussed later. Pathogenesis appears to be dysfunction and focal absence of the corneal endothelium. The two genetic patterns, autosomal dominant and autosomal recessive, have been discussed above. Type I has been mapped to the pericentromeric region of chromosome 20 in the region identified for PPCD, while Type II has been found to be caused by mutations in the SLC4A11 gene which is at a different locus on chromosome 20 (168–174). CHED 2 may also have genetic heterogeneity as cases have been shown without any mutations in the SLC4A11 gene or its promoter region (169,175).

**136.2.6.3 Posterior Polymorphous Corneal Dystrophy (Including Posterior Polymorphous Dystrophy [PPMD], Schlichting Syndrome, Hereditary Deep Dystrophy, Posterior Grouped Vesicles) (IC3D Category 2 [PPCD 1], Category 1 [PPCD 2 and 3]).** Posterior polymorphous corneal dystrophy (PPCD) is characterized by broad pleomorphism, ranging from the presence of small (0.2–0.5 mm) vesicular-appearing opacities that extend posteriorly from Descemet membrane to ridge-like double linear excrescences, to more diffuse Descemet haze. The corneal stroma may be clear, mildly edematous or grossly edematous with overlying epithelial edema. The opacities may be present at birth and may progress over time. Most patients are asymptomatic; changes may be found on routine ophthalmological examination. Others may present with visually disabling edema at birth, or develop edema at any time later in life. Occasional

patients have broad iridocorneal adhesions and some develop open-angle glaucoma. The vast majority of patients require no treatment. Those with mild edema may respond to the use of topical hyperosmotic agents, whereas more extensive edema may prompt penetrating keratoplasty. When glaucoma is present it is treated as typical open-angle glaucoma. When edema is present in infancy, the differential diagnosis is important and is the same as for congenital hereditary endothelial dystrophy. The presence of polymorphous excrescences on Descemet membrane in the affected child and in asymptomatic family members confirms the diagnosis. The corneal endothelium in this disorder is abnormal and forms an epithelial-like multilayered covering to the posterior cornea, which produces abnormal Descemet membrane and may be deficient in barrier and pump function, leading to corneal edema. This may represent an abnormal differentiation of the mesenchymal anlage of the corneal endothelium. A review demonstrated a good prognosis for keratoplasty in patients without iridocorneal adhesions, but a poor prognosis and significant difficulty with glaucoma in grafts on patients with such adhesions. Histopathologically, multiple layers of collagen can be seen on the posterior surface of the Descemet membrane with nodular excrescences. Parts of the endothelium can be replaced by stratified squamous epithelial-like cells. On electron microscopy, thinning or absence of the posterior non-banded layer of the Descemet membrane may be apparent and multilayered epithelial-like cells with desmosomes and microcilia can be seen. Inheritance is usually autosomal dominant, although sporadic cases have been reported and occasional families have been described with autosomal recessive patterns of inheritance. Three loci have been identified for posterior polymorphous corneal dystrophy. A gene locus for PPCD 1 has been linked to 20q11 in the same region as congenital hereditary endothelial dystrophy type I but not type II. VSX1 was previously reported to be the responsible gene, which is also occasionally implicated in keratoconus (176), but a study performed on two large families showed that it was not involved (177). Recent work on mice with a PPCD phenotype showed a 78 base pair duplication in a locus that is syntenic to the human PPCD 1 interval on chromosome 20. It seems to lead to haploinsufficiency of the CSRP2BP gene and resulting PPCD clinical picture, suggesting that the corresponding human gene may have a role in PPCD 1 (178). The same mutation found in Fuchs dystrophy, a Q455K missense substitution in the COL8A2 gene, has also been linked to posterior polymorphous dystrophy (PPCD 2) (154,159). Numerous mutations in the ZEB1 (TCF8) gene in chromosome 10 have been identified as causative for PPCD 3 (179–181). Variable expression and incomplete penetrance has been observed with mutations in this gene (182).

**136.2.6.4 X-linked Endothelial Corneal Dystrophy (IC3D Category 2).** This is a X-chromosomal dominant disorder with congenital onset that affects males more

than females. The male cornea displays corneal clouding that ranges from a milky ground glass appearance to a diffuse corneal haze. Subepithelial band keratopathy along with a moon crater-like appearance in the endothelium can occur. Males may experience nystagmus and often have blurred vision. Females are asymptomatic and only have the moon crater-like endothelial changes. The clinical course tends to be progressive in males and non-progressive in females. A corneal transplant may be needed and the graft usually remains clear, sometimes for as long as 30 years. Histopathology shows irregular thinning of the epithelium and Bowman layer, along with irregularly arranged collagen lamellae in the anterior stroma. Decreased numbers of endothelial cells and irregular thickening of the Descemet membrane, and small excavations and pits have been noted. Electron microscopy shows an abnormal anterior and posterior banded zone in Descemet membrane and a discontinuous endothelial layer. The responsible gene is unknown, but the genetic locus has been determined to be at Xq25 (183).

### 136.2.7 Ectatic Dystrophy

Ectatic dystrophy is added here because the disorder may affect all layers of the cornea and the primary anatomical layer of origin is unknown.

**136.2.7.1 Keratoconus.** In keratoconus there is conical protrusion of the cornea associated with central stromal thinning and irregularity of the corneal surface, as well as anterior stromal scarring and deep stromal fine striations (Figure 136-7). An iron pigment line surrounds the conical area at the level of the basal epithelium. Prevalence of this disorder in the general population is quite high, in one report as high as 1:2000. Typical onset is in the teenage years, with bilateral, often asymmetrical, progressive myopia and astigmatism. Initially, frequent spectacle changes are needed because of the refractive change, but eventually the irregular astigmatism produces inadequate acuity even with spectacles. At that point, rigid contact lenses allow good visual acuity by providing a regular refractive surface. As the conical protrusion of the cornea advances, however, contact lenses may not be well tolerated and acuity may be inadequate. Occasionally, as the disease advances, the Descemet membrane may spontaneously rupture, allowing rapid massive corneal hydration, hydrops, which persists for weeks to months until the Descemet membrane heals over. Although the vast majority of patients have no other associated problems, keratoconus has been described with a myriad of systemic diseases including atopic eczema, trisomy-21, Ehlers–Danlos syndrome, Marfan syndrome, Apert syndrome, and other disorders. Associated ocular disorders include vernal conjunctivitis, pigmentary retinopathy, Leber congenital amaurosis, and aniridia. Histopathological changes include disruption of the epithelial basement membrane and Bowman layer of the stroma with scarring. Confocal microscopy

**FIGURE 136-7** Keratoconus. Note the conical bulging and scarring of the cornea viewed with the patient in down-gaze.

shows an irregular structure of keratocytes in the anterior stroma and electron microscopy has revealed an abnormal electron dense material in the anterior stroma that has not been fully characterized (184).

The pathogenesis of this disorder has been investigated, but remains unknown. Enzyme and collagen cross-linking defects have been suggested as pathogenic. Studies of the biomechanical properties of corneas affected by keratoconus have shown that the stiffness of the anterior 200  $\mu\text{m}$  is decreased compared to a normal cornea (185) and that corneas with keratoconus have fewer cross links compared to normal corneas. Variations in collagen content and levels of protein synthesis in corneas removed at keratoplasty suggest strongly that keratoconus is a heterogeneous disorder. Increases in degradative enzyme levels and reduction in their inhibitor levels have been demonstrated in the epithelium. Exogenous factors, such as eye rubbing, have long been implicated as contributory factors in the development of keratoconus, further complicating genetic linkage studies (186,187). The increasing use of corneal topography, especially in young adults who undergo an evaluation for refractive laser surgery, and detection algorithms for detecting either subtle or forme fruste keratoconus has significantly improved screening and diagnosis.

Surgical intervention, usually in the form of penetrating keratoplasty, becomes necessary to restore good vision when contact lenses can't provide adequate vision, or can't be tolerated and other non-surgical approaches are not an option. To avoid the complications of endothelial rejection, alternatives to penetrating keratoplasty have included epikeratophakia, intracorneal rings, corneal collagen cross linking, and lamellar keratoplasty, with varying success. Deep anterior lamellar keratoplasty (DALK) is being utilized more often in keratoconus. When preparing the host corneal bed, a small amount of residual host stroma may remain on top of the Descemet membrane, resulting in an interface haze postoperatively after the donor button has been sutured into place. In

theory, if the entirety of Descemet membrane is bared, there should be no interface haze since there would be no host stroma remaining to touch the donor stroma. Whether the presence of residual stroma negatively affects the visual outcome is uncertain, with studies not yet providing a consensus (188,189). While the conventional wisdom has held that a penetrating keratoplasty will likely yield a better visual outcome than DALK because of the lack of an interface haze, studies have shown that the answer is still unclear, with some studies pointing to DALK (190,191) and others to PK or showing no significant difference (188,192–194). Corneal collagen cross linking involves the application of riboflavin and ultraviolet light A (UVA) on a de-epithelialized cornea in order to promote cross linking of corneal collagen to stiffen and provide more structural strength within the cornea. Kohlhaas et al. found that the anterior stroma of the human cornea absorbed 65–70% of the UVA light, which corresponded to the area of greatest stiffening (185). Another study showed that the diameter of the collagen fibers was increased in the treated areas, which provided further evidence that cross linking occurs with this treatment (195). European studies in humans have suggested that treatment could halt progression of keratoconus, reduce steepening of the cornea, and result in improved visual acuity with no major adverse events (196–199). Studies investigating the safety of the cross linking showed that corneas should be at least 400  $\mu\text{m}$  thick in order to prevent damage to the endothelium from UVA light. Keratocytes are destroyed down to a depth of approximately 300  $\mu\text{m}$  but repopulate after 6 months. Confocal studies have also shown a loss of corneal nerves anteriorly with regeneration occurring over 6 months (200,201). It has been shown that riboflavin penetrates deeper into the cornea with de-epithelialization (202), but treatment of intact epithelium with the addition of substances that increases epithelial permeability can provide a limited favorable result (203). It is not yet clear how long the effects of cross linking will last and whether retreatment will be needed.

Although the vast majority of cases appear to be sporadic, autosomal dominant and recessive pedigrees have been reported. A positive family history of keratoconus has been reported in 6–10% of patients, but may approach 23% of patients in some areas (204). Fourteen percent of patients in the Collaborative Longitudinal Evaluation of Keratoconus in the US reported a family member with keratoconus. Nonconcordance of keratoconus in identical twins has been infrequently reported. Through linkage studies, a number of loci have been linked to primary or isolated keratoconus (205). One study suggests that patients with Leber congenital amaurosis and a CRB1 mutation may be susceptible to keratoconus (206). As noted under PPCD, multiple mutations of the VSX1 gene on chromosome 20 have been associated with a form of autosomal dominant keratoconus (176). Whether VSX1 is involved in keratoconus (and to what degree) is still debatable, as there are studies that both support and refute a role for this gene (207–211). The SOD1 gene has also been proposed to be a candidate gene (212), but a more recent study did not reveal a pathogenic mutation (209). The SFRP1 gene encodes a protein involved in apoptosis that was recently found to be up-regulated in the corneal epithelium of four patients with keratoconus. Future work will be needed to determine whether this is a true pathogenic mutation (213). Other studies have implicated chromosomes 1 and 8, 2, 3, 5, 13, 14, 15, 16, 20 and 21 in patients with various ethnicities (204,205,214–221). No candidate genes have been identified. It is clear that the disease is complex, significantly heterogeneous, and a single locus is likely not responsible for all observed disease.

### 136.3 DEFECTS ASSOCIATED WITH SYSTEMIC DISEASE

Because defects associated with systemic disease are described elsewhere in much greater detail, attention here is directed to the ophthalmological and, in particular, the corneal abnormalities associated with them. The reader is advised to consult the appropriate chapters concerning the disorder discussed for information about pathogenesis and genetics.

#### 136.3.1 Metabolic Disorders

Metabolic disorders are generally associated with accumulation of an abnormal substance in the cornea. If the substance is produced by the corneal tissues, it may be found throughout the cornea. If it is found in elevated amounts in the blood, it is more commonly accumulated in the corneal periphery.

**136.3.1.1 Lysosomal Storage Diseases.** All three categories of disease described are associated with accumulation of excess material in the lysosomes of the corneal cells.

**136.3.1.1.1 Mucopolysaccharidoses.** Mucopolysaccharides form the ‘ground substance’ that makes up 4–4.5% of the normal cornea. Half of this is keratan sulfate I, which is not found elsewhere in the body. Chondroitin sulfate and chondroitin-4-sulfate account for 25% each. Dermatan sulfate is not present in the normal cornea but is found in corneal scars, rejected grafts and postviral opacifications. In the mucopolysaccharidoses, however, excess dermatan and keratan sulfates appear in the cornea, whereas heparan sulfate accumulates in the retina and central nervous system. Because of deficient lysosomal acid hydrolases, lysosomes accumulate material and cause characteristic pathological changes consisting of intracytoplasmic vacuolation in cells of all corneal layers. In addition, extracellular granular material and accumulation within the cytoplasm occur in both the corneal epithelium and stroma. The degree of corneal clouding characteristic of any given disease is a function of the degree of storage in the keratocytes. All mucopolysaccharidoses that have been studied, even those with clinically clear corneas, have shown the same basic abnormalities. Variations in corneal appearance are related to alterations in the fibrillar arrangement of the corneal stroma. Bone marrow transplant leads to only partial clearing of the cornea and some ocular findings have continued to progress despite bone marrow transplantation. Corneal transplants are usually technically successful, but recurrence is almost assured as early as a 1 year after surgery.

**Type I.** In the Hurler and Scheie syndromes, dermatan sulfate accumulates in the cornea. The corneas are clear at birth, but clouding begins shortly thereafter. The clouding consists of diffuse minute opacities, which give the cornea a ground-glass appearance (Figure 136-8). Although corneal transplants in patients with Scheie syndrome have occasionally remained clear, most have done poorly with time. Patients with clear grafts may still have poor vision because of retinal and/or optic nerve disease. Some studies have shown clear grafts as well as partial clearing of the host corneal rim after penetrating keratoplasty. Enzyme replacement therapy with  $\alpha$ -L-iduronidase has been investigated and its effects on corneal clouding are not yet clear (222).

**Type II.** Hunter syndrome patients with both the mild and severe form have clinically clear corneas, perhaps because of the lesser accumulation of dermatan sulfate. Histopathologically, however, accumulation is seen in the cornea; in the milder form, slit lamp biomicroscopy may demonstrate corneal clouding in older patients.

**Type III.** Sanfilippo syndrome does not accumulate dermatan sulfate, so the cornea is clear on clinical evaluation, although later in life mild stromal haziness may be seen at the slit lamp.

**Type IV.** Morquio syndrome accumulates keratan sulfate, allowing progressive corneal clouding that is similar to that seen in type I.

**FIGURE 136-8** Mucopolysaccharidosis Type I. Note the diffuse corneal clouding seen in a 19-year-old with Hurler–Scheie syndrome.

**Type VI.** Maroteaux-Lamy syndrome accumulates only dermatan sulfate, which leads to a progressive corneal clouding that may be milder than that seen with type I. The differential diagnosis of these disorders is made on the basis of systemic clinical findings and laboratory evaluation. As in type I, clear grafts with partial clearing of the host cornea after penetrating keratoplasty have been reported.

**Type VII.**  $\beta$ -Glucuronidase deficiency is associated with accumulation of both dermatan and keratan sulfates, and corneal clouding is reported to occur in 75% of cases. Corneal transplantation was reported to show good results in terms of clarity in one patient (223). Gene therapy in mice has shown promise in limiting accumulation and, when given locally, improving the clarity of affected murine corneas (224,225).

**136.3.1.1.2 Sphingolipidoses.** Sphingolipidoses, involving abnormalities in ganglioside degradation, are frequently associated with retinal and optic nerve abnormalities. Corneal findings are much less frequently found.

1. Fabry disease is a deficiency in lysosomal hydrolase  $\alpha$ -galactosidase A and has been associated with several ocular findings including retinal and conjunctival vascular abnormalities, lens changes, and papilledema (226). In the cornea, verticillata, a whorl-like haze, is seen in the epithelium of both affected males and female carriers. The opacity has no associated effect on vision. Differential should include drug effects from amiodarone, chloroquine and phenothiazines. Sphingolipid material is seen in the cytoplasm and lysosomes of the corneal epithelium on pathological examination.
2. Other sphingolipidoses, including Sandhoff disease and Niemann-Pick disease, may rarely show corneal clouding, although corneal involvement can be

demonstrated on pathological examination. Corneal opacities had been reported in Gaucher disease associated with calcific cardiac valvular disease (D409H variant).

**136.3.1.1.3 Mucolipidoses.** In muculipidoses (MLS), mucopolysaccharides and sphingolipids and/or glycolipids accumulate. Corneal clouding similar to that seen in the mucopolysaccharidoses may thus be seen in combination with the classic retinal cherry-red spot and central nervous system abnormalities. In GM<sub>1</sub> gangliosidosis, keratan sulfate accumulation in the cornea may lead to mild corneal clouding. In MLS II, corneal clouding may be seen occasionally clinically, whereas pathological evaluation reveals accumulation of granular material in the cornea even in clinically clear specimens. MLS IV has much more prominent corneal clouding, which may present early in the first year of life. MLS types I and III less commonly have corneal findings. The syndrome described by Goldberg et al. (1971) combines corneal clouding and a macular cherry-red spot. The variant form of metachromatic leukodystrophy also shows corneal clouding. Conjunctival biopsy may help to confirm the diagnosis with the demonstration of single membrane-limited vacuoles filled with fibrogranular material and lamellar bodies. Involvement of the corneal endothelium has also been reported (227). Recurrence after penetrating keratoplasty is rapid, likely because of the replacement of the donor epithelium with opaque recipient epithelium. In a patient with MLS IV, related unaffected donor conjunctival transplantation was reported to improve corneal clarity.

**136.3.1.2 Protein and Amino Acid Metabolic Abnormalities.**

**136.3.1.2.1 Cystinosis.** In the infantile form of cystinosis, multiple fine polychromatic needle-like crystals are seen in the anterior corneal stroma and in the

conjunctiva in the first year of life, whereas in the adolescent and adult forms they appear much later but have the same clinical appearance. Mild photophobia without visual deficit may occur in all forms, but is most common in the infantile form. Conjunctival biopsy with fixation in absolute alcohol may be used to confirm the diagnosis. Distinction must be made between these crystals and those seen in crystalline dystrophy, gout, and multiple myeloma. In patients with nephropathic cystinosis, renal transplantation does not appear to alter the progressive deposition of cystine crystals in the cornea and, as life expectancy has increased, so have the severity of ocular manifestations (228). Mutations in the cystinosis gene allelic with those of nephropathic cystinosis have been found in patients with ocular non-nephropathic cystinosis (229). Topical cysteamine eye drops promote clearing of crystals from the cornea (229,230). Unfortunately cysteamine oxidizes rapidly at room temperature to cystamine, which is ineffective, making this disorder more difficult to treat.

**136.3.1.2.2 Amyloidosis.** Amyloidosis is discussed in the section on lattice corneal dystrophy.

**136.3.1.2.3 Tyrosinemia Type II, Richner–Hanhart Syndrome.** The type II form of tyrosinemia has as a prominent feature marked photophobia and tearing with the development of branching central intraepithelial and subepithelial corneal opacities and ulcers. The lesions may present in the first decade of life and decrease over the next few decades. The lesions disappear on a diet low in phenylalanine and tyrosine and appear to be due to accumulation of tyrosine crystals within epithelial cytoplasmic membrane-bound inclusions. Untreated Type I form of tyrosinemia does not induce ocular symptoms because tyrosine is not accumulated at the same levels with the enzymatic defect well ‘downstream’ in the metabolic pathway. Treatment with NTBC (2-(2-nitro-4-trifluoromethylbenzoyl)-1,3 cyclohexane dione), which inhibits the catabolism of tyrosine, is life-saving for these individuals, but can lead to a type II-like corneal presentation during childhood (231).

**136.3.1.2.4 Wilson Disease.** Although the ocular changes in this disorder are asymptomatic, they may alert the physician to the diagnosis. Yellow-brown, gold, or green deposition of copper occurs in the periphery of Descemet membrane and extends centrally for 1–3 mm in the Kayser–Fleischer ring. The ring may disappear with systemic treatment or liver transplantation, but Kayser–Fleischer ring reduction does not directly correlate with or predict clinical improvement in neuropsychiatric manifestations of Wilson disease. The same corneal findings can also occur in acquired liver disease with secondary copper transport impairment.

**136.3.1.2.5 Lowe Syndrome.** Although glaucoma and cataract are the classical ocular findings, dense corneal scarring with a dense white vascularized opacity in

the lower portion of the cornea occurs toward the end of the first decade of life. This may represent scarring secondary to corneal edema induced by the glaucoma; more likely, it is secondary to the prolonged digital-ocular manipulation seen in these children.

**136.3.1.2.6 Familial Dysautonomia, Riley–Day Syndrome.** Because of their severe tear insufficiency, corneal insensitivity to pain, and decreased frequency of blinking, these patients have trouble with recurrent corneal ulceration, with ultimate corneal scarring and vascularization. Tear replacement, lubricating ointments, punctal occlusion, and tarsorrhaphies may help to decrease the corneal complications.

### 136.3.1.3 Lipid Metabolic Abnormalities.

**136.3.1.3.1 Hyperlipoproteinemias.** In the hyperlipoproteinemias, corneal findings may aid in the initial diagnostic suspicion. *Corneal arcus* is the term used to describe the deposition of phospholipids, cholesterol esters, and triglycerides in the corneal periphery at all levels, but most markedly at the level of Descemet and Bowman layers. Most commonly, this is seen as a normal aging phenomenon, but its presence before the age of 30 or 40 should prompt evaluation of lipid metabolic function. Fredrickson types II–V may have arcus, whereas types I and II may have more extensive lipid infiltration of the cornea (termed ‘lipid keratopathy’). Xanthelasma may occur in types II–IV. All these changes may be due primarily to elevated cholesterol. Markedly elevated triglyceride, as can occur in all but type II, is associated with lipemia retinalis, the milky appearance of blood in the retinal vessels.

**136.3.1.3.2 Lecithin Cholesterol-Acyltransferase Deficiency.** Lecithin cholesterol-acyltransferase deficiency may be associated with an accumulation of diffuse gray dot-like opacities in the corneal stroma that is denser in the periphery. Bilateral corneal opacity becomes more evident with age and penetrating keratoplasty specimens exhibit secondary amyloidosis present throughout the stroma (232). A different defect at same locus leads to fish-eye disease, with much more extensive corneal opacification.

**136.3.1.3.3 Tangier Disease.** In  $\alpha$ -lipoprotein deficiency, the accumulation of cholesterol esters in the tissues, despite abnormally low serum levels, leads to the development of a corneal stromal haze that consists of many fine dots and is denser in the posterior stroma.

## 136.3.2 Corneal Abnormalities Associated with Other Inherited Syndromes

### 136.3.2.1 Cutaneous Disorders.

**136.3.2.1.1 Ichthyosis.** Corneal findings in ichthyosis vulgaris are uncommon. In X-linked ichthyosis, dense deep corneal stromal dot-like opacities can be seen on slit lamp examination; these are asymptomatic.

**136.3.2.1.2 Ectodermal Dysplasia.** Anhidrotic ectodermal dysplasia is associated with decreased tear production, secondary punctate epithelial corneal erosion and peripheral corneal vascularization. In some forms of ectodermal dysplasia, limbal stem cell dysfunction may lead to corneal opacification.

**136.3.2.1.3 Epidermolysis Bullosa.** Corneal scarring and pannus are frequent in the autosomal recessive dystrophic form and the junctional form. Peripheral corneal vascularization can be seen in the simplex form in a small proportion of patients.

**136.3.2.1.4 Xeroderma Pigmentosum.** Because of the failure of epithelial repair after actinic damage, these patients experience severe photophobia, and drying and scarring of the conjunctiva and cornea. At times, they may also develop anterior stromal corneal nodules. Malignant neoplasms frequently develop in the conjunctiva and cornea.

## 136.4 OTHER INHERITED CORNEAL ABNORMALITIES

Several congenital anomalies can involve the cornea. A few with inheritance are mentioned here.

### 136.4.1 Megalocornea

In megalocornea, non-progressive enlargement of the cornea to a diameter greater than 13 mm is seen in the absence of glaucoma. Occasionally, other anterior segment anomalies may be associated. It is important to differentiate this disorder from the progressive buphthalmos of congenital glaucoma. Inheritance is usually X-linked recessive, although autosomal dominant and autosomal recessive pedigrees have been reported.

### 136.4.2 Cornea Plana

In cornea plana, unusually flat and often smaller-than-normal corneas are present at birth. In addition, there is often sclera-like opacification of the cornea either peripherally or throughout. Anterior segment developmental abnormalities may also be present. Visual acuity is usually poor. Although commonly autosomal dominant, autosomal recessive inheritance has also been reported.

It can be seen in the MIDAS syndrome, which is an acronym for microphthalmia, dermal aplasia, and sclerocornea (233,234). The dermal aplasia usually consists of linear erythematous skin defects involving the face, scalp, neck and thorax. Non-ocular abnormalities such as cardiac anomalies, short stature, and absence of the corpus callosum can also be seen. This disorder is thought to be X-linked dominant, with deletions or unbalanced translocations involving Xp22.3 (235). It mainly occurs in females as it appears to be lethal in hemizygous males. Phenotypic heterogeneity in ocular findings have been reported (233).

### 136.4.3 Others

Many other anterior segment abnormalities with familial tendencies occur, including Axenfeld-Rieger, Peters, and other anterior chamber cleavage anomalies. Peters anomaly is a disorder with a congenital defect in the posterior cornea, corneal opacification, iris adhesions to the cornea, and, in some patients, lens developmental abnormalities. PAX6 gene mutations have been found in some patients with this disorder as well as in aniridia and dominantly inherited keratitis. Most patients with Peters anomaly, however, have normal PAX6 genes. Because of limitation of space here, the reader is referred to other articles the work of Waring, Rodrigues, and Laibson (1975) for a thorough discussion of these disorders (236–239).

## 136.5 CONCLUSION

Many inherited corneal defects can occur both as isolated findings and in association with systemic disease. An awareness of these is important to the general physician and geneticist as well as to the ophthalmologist.

## GLOSSARY

- Aphakia** – absence of the crystalline lens of the eye, either as a result of surgery or as a primary condition.
- Cataract** – a loss of clarity of the crystalline lens of the eye.
- Ectopia lentis** – displacement of the crystalline lens out of its usual position.
- Microspherophakia** – a lens that is smaller and rounder than normal.
- Autosomal dominant** – Mendelian inheritance pattern in which one abnormal copy of a gene causes disease.
- Autosomal recessive** – Mendelian inheritance pattern in which two abnormal copies of a gene cause disease.
- X-linked inheritance** – also called X-linked recessive. Inheritance of a gene on the X chromosome which is expressed in males more severely than females due to their lack of an additional X, rendering them hemizygous for the allele.

## 137.1 INTRODUCTION

The lens is a transparent crystalline structure responsible for transmitting light rays to the retina, which in turn transmits visual impulses to visual cortex via the optic nerve and visual pathways. It accounts for one-third the refractive power of the eye, the clear cornea accounting for the other two thirds. By far the most common anomalies of the lens are varying degrees of opacification, commonly referred to as cataracts. Other anomalies are much rarer; these include absence of the lens (aphakia), colobomas, abnormalities of the embryonic vascular system (persistent pupillary membrane, Mittendorf dot, persistent fetal vasculature), anomalies of shape (lenticonus, spherophakia), anomalies of size (microspherophakia), and dislocation of the lens (ectopia lentis). Anomalies of the lens can be divided into two major subgroups: (1) noncataractous anomalies and (2) cataracts.

## 137.2 NONCATARCTOUS ANOMALIES

The group of disorders known as noncataractous anomalies is summarized in [Table 137-1](#). Although the precise correlation between this group of disorders and the embryological development of the eye has not been demonstrated, it would be reasonable to assume that many of these anomalies can be explained by mechanisms that interfere with the embryologic development of the lens, as summarized in [Table 137-2](#) and depicted in [Figure 137-1](#).

While elongating, the anterior ends of cells in the developing lens move toward the anterior pole of the epithelial layer; the posterior ends move along the posterior capsule toward the posterior pole. Thus, the newer constituents of the lens surround the preexisting parts, and no cells formed in the lens are shed or extruded. The lens thus keeps a record of its complete cellular history, with the oldest portion innermost. This explains why lens opacities that develop during a limited period in the superficial (cortical) lens are later buried as opaque layers in the inner lens region, covered by a newly formed clear superficial layer (so-called nuclear or zonular cataracts). It is even possible to estimate the time of cataract formation from its relative depth within the lens. Cataracts may now be identified in utero by obstetrical ultrasound as early as 14 weeks gestation ([1](#)).

### 137.2.1 Congenital Aphakia

Congenital aphakia (absent lens) can result from lack of development of the lens anlage (primary aphakia) or pre-natal resorption of an abnormally developed lens (secondary aphakia). We have observed a case in a patient with Fraser cryptophthalmos syndrome at Cedars-Sinai Medical Center, in Los Angeles. We have also observed a child at the University of Iowa with bilateral lens

resorption in whom only an anterior capsule was present; the child's anterior segments appear normal other than small corneal diameters, and he has no other congenital anomalies. Recurrent phimosis of the capsular opening has occurred postoperatively. Congenital aphakia has been reported as a recessive disorder in a strain of mutant mice mapping to mouse chromosome 19. The responsible gene is *Pitx3*, due to a mutation in a promoter of the homeobox transcription factor; a mutation in the analogous *PITX3* gene in humans causes cataract and anterior segment dysgenesis (ASD) (2,3). Mutations in the *FOXE3* gene can cause autosomal recessive congenital aphakia in humans (4). Mutations or deletions in the *TFAP2A* gene in humans have been reported to cause autosomal dominant primary aphakia (5). These eyes also had other anomalies. The analogous gene in mice has been shown to be important in formation of the lens and in tissue–tissue interactions and development of the entire eye during embryogenesis (6). Because the lens plays a role in stimulating the growth and development of the anterior segment, these eyes are smaller than normal (microphthalmic). Lens coloboma consists of a circumscribed indentation of the lens equator (Figure 137-2). The zonule is usually defective in this region; uveal colobomata may be found in association. Dominant inheritance has been reported, occurring in individuals with associated ectopia lentis (7). c-Jun NH(2)-terminal kinase (JNK), a terminal kinase group of mitogen-activated protein kinases, initiates a cascade that causes Pax2 expression important in closure of the optic fissure (i.e. a disturbance in this cascade causes coloboma formation) (8). Colobomas of the eye are more common than previously thought, with an incidence of 1/2077 live births reported in Olmstead County (9). Lens coloboma may be associated with chorioretinal colobomas and commonly has an overlying iris coloboma and frequently cataract in the affected area of the lens. One in eight patients with ocular coloboma has CHARGE

**TABLE 137-2 Embryologic Development of the Human Lens (A Structure Entirely of Ectodermal Origin)<sup>a</sup>**

1. Week 3 (4-mm stage)—Formation of lens anlage begins with elongation of ectodermal cells at site where the optic cup touches the ectoderm to form the lens plate (Figure 137-1A).
2. Week 4 (7-mm stage)—Lens plate invaginates to form the lens pit.
3. Week 5 (11-mm stage)—Lens pit is sequestered from the surface ectoderm to form the lens vesicle (Figure 137-1B); The lumen of the lens vesicle is then obliterated by the elongation of the posterior cell layers into “fiber”-like cells (“primary” lens fibers (Figure 137-1C)).
4. Week 7 (20-mm stage)—“Primary” lens fibers reach from the posterior lens surface to the anterior cell layer, which maintains its epithelial character; an exclusively epithelial structure is thus formed covered on the outside by the basal membrane, which increases in thickness to form the lens capsule (Figure 137-1D).
5. Rest of fetal period and lens increases logarithmically in weight and volume by apposition of new lens material at the postnatal life equator; only the pre-equatorial region of the anterior epithelium divides and newly formed are pushed onto the lens equator, where they start to elongate into new (secondary) lens fiber cells (Figure 137-1E).

<sup>a</sup>While elongating the anterior ends of these cells move toward the anterior pole of the epithelial layer while the posterior ends move along the posterior capsule toward the posterior pole. Thus, the newer constituents of the lens surround the preexisting parts and no cells that have been formed in the lens are shed or extruded. The lens thus keeps a record of its complete cellular history, the oldest portion being innermost. This explains why lens opacities that develop during a limited period of time in the superficial (cortical) lens are later buried as opaque layers in the inner lens region, covered by a newly formed clear superficial layer (so-called nuclear or zonular cataracts). It is even possible to estimate the time of cataract formation from its relative depth within the lens (Koch et al., 1983) (53).

**FIGURE 137-1** Lens development in the rat. A, Formation of lens plate at day 11. B, Formation of lens vesicle at day 12. C, Beginning of elongation of posterior lens epithelium to form fiber cells at day 13. D, Obliteration of lens vesicle by elongated "primary" lens fibers at day 14. E, Appositional lens growth by formation of "secondary" lens fiber cells from the equatorial region at day 18. Human lens development is similar, except for timetable.

syndrome (9), which may be caused by mutations in the CHD7 gene (10). Persistent pupillary membranes (Figure 137-3) and Mittendorf dots (Figure 137-4) are remnants of the primitive vascular supply of the lens (tunica vasculosa lentis or posterior hyaloid vessels). All of this vascular system is usually resorbed, and these two entities remain as a result of interference with the resorption process (11). A Mittendorf dot is usually seen just behind the posterior lens capsule, inferonasal to the center of the

**FIGURE 137-2** Lens coloboma in a patient with Marfan syndrome.

**FIGURE 137-3** Persistent pupillary membrane with associated anterior polar cataract.

**FIGURE 137-4** Mittendorf dot, located behind the posterior capsule.

lens. Both conditions are sporadic and usually are of no visual consequence to the patient.

### 137.2.2 Lenticonus

Lenticonus consists of a bulge in the front of the lens (anterior lenticonus) (Figure 137-5) or at the back of the lens (posterior lenticonus) (Figure 137-6). Anterior lenticonus is associated with Alport syndrome. This multisystem disorder has three major findings: chronic nephritis, nerve deafness, and specific ocular abnormalities. The common denominator is that basement membranes are affected in all three organs (12). Electron microscopy studies have shown abnormalities of the lens epithelium in Alport syndrome to include dilated Golgi complexes and rough endoplasmic reticulum, swollen mitochondria, increased tonofilaments, and absence of epithelial cells under the lens capsule (13). The anterior lenticonus is bilateral in 75% of patients, and typically, it is acquired, appearing in the 20- to 30-year age range with symptoms of increasing myopia (14). In addition to anterior lenticonus, other ocular abnormalities seen in Alport syndrome include arcus cornealis, posterior subcapsular cataracts (PSCs), myopia, and whitish gray dots in the macula. The inheritance pattern is complex, with X-linked, autosomal recessive and autosomal dominant forms. The X-linked form, found in 80% of patients, is due to a mutation in the gene *COL4A5* located at Xq22 encoding a type IV collagen a chain. The mutation causing autosomal recessive Alport syndrome was traced to *COL4A3* and autosomal dominant Alport syndrome to *COL4A4*, both on chromosome 2 (14,15). A variant of anterior lenticonus, known as anterior polar cataract, has been described in a patient with Ehlers-Danlos syndrome (16). Isolated, small flat anterior polar cataracts may be autosomal dominant and may not cause visual disturbance other than hyperopia. Posterior lenticonus is usually sporadic and of unknown pathogenesis (17). It is typically unilateral; however, there are reports of familial cases, in which it is bilateral with an autosomal dominant mode of inheritance, or possibly X-linked (18). Clinically, it appears as an “oil drop” phenomenon, with posterior cortical cataract found in front of the lenticonus in about 80% of cases. Increasing myopia is often an early sign. Visual acuity is usually decreased early in life, and associated amblyopia and strabismus are common. Posterior lenticonus has been reported with Alport syndrome and Pierson syndrome (15,19). Recently, bilateral posterior lenticonus in a child with a chromosomal translocation was found to be caused by disruption of the *TDRD7* gene; this gene was found to be expressed in the posterior lens capsule in chicks and mice and mutation causes cataract and glaucoma in mice (20).

### 137.2.3 Microspherophakia

The normal crystalline lens is thicker in the middle than at the edges. When instead it is round, it is known as

**FIGURE 137-5** Anterior lenticonus in a patient with Alport syndrome.

**FIGURE 137-6** Posterior lenticonus.

spherophakia, and if it is small as well, it is known as microspherophakia (Figure 137-7). Some ultrastructural studies do not show such lenses to be simply small and round but also wider posteriorly and narrower in front—the exact opposite of normal.

Microspherophakia is the typical manifestation of Weill-Marchesani syndrome; however, it may rarely be an isolated phenomenon or associated with another syndrome. The lens may be subluxated or dislocated. Ocular abnormalities reported with microspherophakia include lenticular myopia, angle-closure glaucoma, poor accommodative reserves, and tapetoretinal degeneration, while systemic associations include arachnodactyly, dwarfism, beaked nose, microstomia, micrognathia, and mental retardation (21,22). The mode of inheritance may be autosomal dominant or recessive. Isolated microspherophakia has been reported to be caused by mutations in the *LTBP2* gene (23).

**FIGURE 137-7** Microspherophakia in a patient with Weill–Marchesani syndrome.

### 137.2.4 Ectopia Lentis

Ectopia lentis (subluxation of the lens) can appear as an isolated phenomenon, associated with an ectopic pupil only, or a manifestation of a number of multisystem disorders (see [Table 137-1](#)). A Danish review of ectopia lentis (EL) gave a prevalence rate of 6.4 per 100,000 live births. Etiology was determined in 69% of these cases with the following results: Marfan syndrome 68.2%, ectopia lentis et pupillae 21.2%, isolated dominant ectopia lentis 8%, and homocystinuria, sulfite oxidase deficiency, and Weill–Marchesani syndrome each comprising approximately 1%, with the remaining 31% of indeterminate etiology ([24](#)). Three different types of inherited bilateral isolated ectopia lentis can be distinguished: a congenital dominant form, in which most lenses are displaced upward; a congenital recessive form; and a late-onset dominant form, in which subluxation occurs between ages 20 and 65, with subluxation usually occurring inferiorly. Studies in multiple families with isolated ectopia lentis and lacking any clinical or echocardiographic signs of Marfan syndrome demonstrated a point mutation in *FBN1* (the gene for fibrillin) on chromosome 15 ([25–27](#)). Some of the more common syndromes which include ectopia lentis are discussed below. Other very rare conditions in which ectopia lentis occurs should be considered in the differential diagnosis if the preceding three conditions have been excluded are familial hyperlysinemia, sulfite oxidase deficiency, molybdenum cofactor deficiency, Ehlers–Danlos syndrome, Wildervanck syndrome, and Kniest dysplasia (metatropic dwarfism type II). In patients suspected of having these syndromes (e.g. sulfite oxidase deficiency) the ophthalmic examination is key, as dislocation of the lenses may be one of the early presenting signs ([28](#)).

Ectopia lentis et pupillae is a rare autosomal recessive disorder in which subluxation of the lens is associated with a displaced pupil (corectopia). The condition is congenital, usually nonprogressive, bilateral, and symmetric. In addition, patients have microspherophakia, miosis, and

**FIGURE 137-8** Ectopia lentis in a patient with Marfan syndrome (superotemporal dislocation).

poor pupillary dilation with mydriatics. Displacement of the lens may be in any direction, and the edge of the lens often bisects the pupil, causing diplopia and poor vision. There is often an associated increased transillumination of the iris periphery. All the affected ocular structures—the lens zonules, iris dilator muscles, and the posterior pigmented layer of the iris—have a common embryologic origin (i.e. the neuroectodermal layer). Mutations in the *ADAMTSL4* gene, as well as *FBN1*, are now known to cause ectopia lentis et pupillae ([29](#)).

Isolated ectopia lentis is relatively rare; more commonly, this is associated with a multisystem disease or an inborn error of metabolism. The common denominator appears to be a weakness of the zonules caused by an inherited disorder of connective tissue or an enzymatic deficiency. Studies have shown significantly decreased amounts of fibrillin in the lens capsules of patients with *Marfan syndrome*, as well as abnormal, disrupted fibrillin fibers in the lens capsule ([30](#)). The finding of a deletion in the fibrillin-1 (*FBN1*) gene of one autosomal dominant Weill–Marchesani syndrome family demonstrates that autosomal dominant Weill–Marchesani syndrome and Marfan syndrome are allelic conditions ([31](#)).

Although an extensive list of disorders reported to be associated with ectopia lentis is summarized in [Table 137-1](#), this discussion focuses only on the ocular manifestations of three most commonly associated multisystem diseases: Marfan syndrome, homocystinuria, and Weill–Marchesani syndrome.

In Marfan syndrome (see Chapter 153), a dominant disorder with skeletal, cardiovascular, and ocular anomalies, lens displacement occurs most commonly superiorly ([Figure 137-8](#)), although it can occur in any direction, including into the vitreous. Ectopia lentis occurs in

approximately 70% of Marfan patients and is often congenital, but it may occur later in life, progressing with the growth of the globe. Other ocular findings include enophthalmos, axial myopia, flat corneas, glaucoma, and peripheral retinal degenerative changes, with an increased incidence of retinal detachment in both phakia and aphakia. In rare cases, lens colobomas and spherophakia may be associated. Ocular manifestations tend to be bilateral and fairly symmetric. Many phenotypic variations of Marfan syndrome exist. Phenotypic variants of Marfan syndrome may be due to different mutations within the fibrillin-1 gene (32) or abnormal fibrillin microfibril morphology and assembly (33). These clinical variants may be referred to as type 1 fibrillinopathies, and the respective mutations are accessible via the international Marfan database (<http://www.umd.necker.fr>) (34).

The lens subluxation in *homocystinuria*, an inborn error of metabolism, occurs most commonly inferiorly (Figure 137-9) although it can occur in any direction. Ectopia lentis occurs in 90% of untreated homocystinuria patients. Other contrasting features to the ocular findings in Marfan syndrome include the following: (1) the zonules are weak, and dislocations occur more commonly into the anterior chamber; (2) lens displacement is not congenital but occurs during childhood or adulthood and may be progressive; and (3) patients have no abnormal angle structures. Glaucoma occurs in up to 25% of patients and is usually caused by a pupillary block mechanism secondary to lens dislocation. Other ophthalmic manifestations of homocystinuria include optic atrophy in 23% of patients, iris atrophy in 21%, anterior staphylomas in 13%, and lenticular and corneal opacities, each in 9% (35). Although the body habitus of patients with homocystinuria resembles that of Marfan syndrome, these patients may develop intellectual impairment, and increased levels of homocysteine and homocystine are found in their urine. The disease is commonly caused by an enzymatic deficiency of cystathionine b-synthetase.

In Weill–Marchesani syndrome, the lens dislocation is usually inferior. These patients are easily distinguished from patients with Marfan syndrome or homocystinuria because of their antithetical body habitus, consisting of short stature, short and wide fingers, and short and large chest (36,37). Other ocular abnormalities include angle-closure glaucoma due to peripheral anterior synechiae or to pupillary block from the lens dislocation. Myopia due to the small and round lens is also a common accompaniment (38). Weill–Marchesani syndrome has been described in both autosomal recessive and autosomal dominant forms. A locus for autosomal recessive Weill–Marchesani syndrome has been mapped to 19p13.3–p13.2, and a mutation in the fibrillin-1 gene (15q21.1) was found in two autosomal dominant Weill–Marchesani families. Differences between the autosomal recessive (AR) and autosomal dominant (AD) families were found in clinical presentation of microspherophakia (94% in AR vs 74% in AD) and ectopia lentis (64%

**FIGURE 137-9** Ectopia lentis in a patient with homocystinuria (inferior dislocation).

in AR vs 84% in AD) that were statistically significant, but not for myopia, glaucoma, or cataract (39). One gene associated with the autosomal recessive form is ADAMTS10, while FBN1 has been reported to be associated with the dominant form (40).

### 137.3 CATARACTS

A cataract is an opacification of the lens resulting in distorted and blurred vision (Figure 137-10). By far the most common cataract occurring in humans is the age related or senile cataract, caused by progressive opacification of the lens in adulthood. While genetic factors play a role in its development, it is a multifactorial and probably polygenic disorder. Environmental factors such as ultraviolet (UV) radiation from sunlight are thought to play an important etiologic role. Age-related cataract is so common that it is generally not regarded as a genetic disorder. Twin and sibling studies of age-related cataract have shown that genetic risk factors likely play a role in many cases of nuclear and cortical cataract. In addition, variations in at least eight genes known to cause inherited infantile and juvenile cataracts have been linked to age-related cataract (41).

From a genetic perspective, there are four important types of cataract: isolated hereditary congenital cataracts, cataracts associated primarily with ocular disorders, cataracts associated with genetic syndromes, and cataracts associated with metabolic disorders. The formal definitions of infantile, developmental, juvenile and congenital cataracts differ somewhat. It is useful to think

*A cataract is a clouding of the eye which causes vision to be distorted and blurred.*

**FIGURE 137-10** Illustration of the optical effects of a cataract.

of congenital and infantile cataracts as those that occur within the first year of life. This discussion uses the terms congenital and infantile interchangeably. Juvenile cataract generally means a cataract with onset in the first decade of life. Presenile cataracts are those that present before approximately 45 years of age and those that present after 45 years are considered age related or senile (42).

Congenital cataracts are one of the few true emergencies in pediatric ophthalmology. This is because in order to get a good visual outcome, surgery to remove the cloudy lens, and optical correction to replace it, must be achieved before 4 months of age. This requires early detection, preferably in the newborn nursery. Since virtually all bilateral congenital cataracts are genetic, either as isolated lens or ocular disorders, or part of a syndrome, there is also an urgent need for genetic counseling and guidance on surveillance, services, and prognosis for these families. We now know that almost 200 different genes and loci play a role in cataracts (41), yet we still do not have a means of routinely testing these children, making counseling a challenge. While most cases are autosomal dominant, an important minority are autosomal recessive and X-linked. The important finding that some mutations of the Nance-Horan Syndrome gene can cause isolated congenital cataract broadens the testing and counseling landscape. When there systemic

anomalies associated, the list of testable genes increases. This is true when there are specific related ocular findings as well. In some families, congenital cataract may be the most obvious sign of aniridia, caused by *PAX6* gene mutations. These eyes also have some degree of iris hypoplasia and foveal hypoplasia, as well as a high risk of corneal anomalies and glaucoma. Several other genes have also been implicated in anterior segment dysgenesis associated with congenital cataracts.

Congenital cataracts are responsible for approximately 10% of all blindness in children worldwide (43). One in 250 newborns has some form of congenital cataract, although some of these are not clinically significant. A national surveillance system in the United States that monitors hospital discharge data for birth defects (the Birth Defects Monitoring Program [BDMP]) demonstrated a prevalence of neonatal cataracts from 1988 to 1991 of 1.2 per 10,000 births (43). Some authors believe this statistic to be an underestimate (44). A Spanish study (45) yielded a figure of 6.31 per 100,000, in a study of over one million consecutive births between 1980 and 1995, as detected within the first three days of life. In contrast, a French study of 131,760 consecutive births yielded a figure similar to the US study, with 2.3 per 10,000 births (46). Studies in the United Kingdom (47) showed that a substantial proportion of congenital and infantile cataracts were initially missed, despite a national plan for routine screening. Other large studies from the United Kingdom and Australia both estimated the incidence to be between 2.2 and 2.49 per 20,000 live births (47,48). Variations in the figures demonstrate the difficulties in diagnosing neonatal cataracts. In the United States, the onus for diagnosing congenital cataracts usually falls on pediatricians, who are charged with assessing the red reflex of all newborns before discharge from the hospital. In one study, only 57% of congenital cataract patients were examined by an ophthalmologist by 3 months and 33% were not evaluated until after 1 year of life. In addition, documentation of surveillance and identification in large-scale studies is difficult, although it may be improved with capture-recapture type of data collection (49). A screening of 2447 4-year-olds yielded a prevalence of 7.7 cataracts per 10,000, indicating that symptoms leading to diagnosis or repeated examinations may increase the diagnostic yield. Of these cataracts identified, 40–55% were unilateral.

It was found that 15% of visually handicapped children have congenital cataract (Figure 137-11) (50). About 25–50% of congenital cataracts are hereditary, but a patient with a congenital cataract must undergo a complete workup to rule out other causes before this is determined (51). About 15% of congenital cataracts are associated with a multisystem syndrome, 70% are isolated, and another 15% are associated with abnormalities of other parts of the eye (42). A suggested clinical approach is outlined in Table 137-3.

### 137.3.1 Classification

Congenital cataracts can be classified according to morphology. For simplification, these can be divided into four broad categories: zonular, polar, total (mature), and membranous (51). Zonular cataracts involve one zone of the lens and can be subdivided into nuclear (Figure 137-12), lamellar (Figure 137-13), sutural (Figures 137-14 and 137-15), spear-like, coralliform, floriform, and capsular cataracts. The nuclear type is often bilateral and is usually associated with a significant decrease in visual acuity. The lamellar subtype (by far the most common type of congenital cataract) is characterized by an opaque layer surrounding a relatively clear nucleus. Lamellar cataracts are typically bilateral but slightly asymmetric, and generally have autosomal dominant inheritance (52). They may or may not severely affect vision. Sutural cataracts (involving the Y sutures) and small capsular cataracts often do not affect vision. Sutural cataracts are occasionally found

**FIGURE 137-12** Central pulverulent nuclear cataract.

**FIGURE 137-13** Lamellar cataract.

in asymptomatic relatives of affected patients. Autosomal dominant zonular cataracts with sutural opacities have been mapped to chromosome 17q11–12, near the beta A3/A1 crystallin gene (53). Aculeiform cataracts are punctate, needle-like cataracts, which are morphologically similar, but distinct from coralliform cataracts. They are usually bilateral with dominant inheritance, complete penetrance, and variable expressivity. The aculeiform cataract maps to the  $\gamma$ -crystallin gene (*CRYGD*) on chromosome 2q33–35, which lies in close proximity to *CRYBA2* (54).

Polar cataracts involve either the anterior (Figure 137-16) or posterior (Figure 137-17) pole of the lens and affect the capsule and underlying lens with limited visual detriment if they are less than 3 mm in diameter, although anterior polar cataracts may be associated with corneal astigmatism and hyperopia. Autosomal dominant anterior polar cataracts were associated with a 2;4 translocation in one family and were localized to 17p12–13 in another family (55). They may also occur sporadically. Anterior pyramidal cataracts are a subset of anterior polar cataracts, involving the capsule and lens in a hyperplastic, conical fashion. Reported in both

normals and Ehlers–Danlos patients, these cataracts are more visually significant than smaller, flatter anterior polar cataracts (16). They may be unilateral or bilateral (56). In total cataracts, the entire lens is opaque and is associated with poor visual acuity and nystagmus. Total cataracts may be found in Down syndrome, metabolic cataracts, congenital rubella, and rarely as a severe Mendelian cataract, as well as sporadically. Membranous cataracts involve an opaque, thin, fibrotic lens caused by resorption of lens protein and subsequent thinning in the anteroposterior direction of the lens. The anterior and posterior capsules fuse to form a dense white membrane. This condition may be associated with other ocular abnormalities, including PHPV, aniridia, and decompensated lenticonus, as well as with systemic syndromes including congenital rubella, Hallerman–Streiff, or Lowe syndromes. Cerulean cortical cataracts have been linked to mutations in the  $\beta$ -crystallin gene on human chromosome 22q (52). A second site for cerulean

FIGURE 137-14 Sutural cataract (Y suture) female carrier.

FIGURE 137-15 Sutural cataract (Y suture) male.

FIGURE 137-16 Anterior polar cataract.

FIGURE 137-17 Posterior polar cataract.

cataracts was found on chromosome 17q24. A suture sparing congenital nuclear lenticular bilateral cataract phenotype was found in a large five-generation Swiss family, which was linked to chromosome 17, D17S1857 and found to be due to a *CRYBA3/A1* gene mutation (57). Morphological classification may help indicate age of onset, inheritance, etiology, or prognosis. Post-surgical visual outcomes have been found to portend a better prognosis in certain types of congenital cataract (specifically lamellar, pulverulent, polymorphic, coraliform, and cortical), which is important to address in clinical counseling (58). While age-related cataracts have a relatively narrow range of phenotypes—typically nuclear, cortical, posterior subcapsular, or combinations thereof—because they represent senescence of a normally formed crystalline lens, infantile cataracts are extremely polymorphic. They represent disruption of the normal formation of the lens.

### 137.3.2 Molecular Genetics

Isolated hereditary congenital cataracts can display any of the preceding morphologic subtypes (Figures 137-12 to 137-17). Although this classification is somewhat

artificial for congenital hereditary cataracts, and there is marked heterogeneity for both type and degree of cataract formation even within families, it is a useful clinical approach for identifying the various subtypes. Hereditary cataracts caused by the same gene can have very different morphology, even in members of the same family, while cataracts caused by different genes can appear similar.

Isolated congenital hereditary cataracts may be transmitted as autosomal dominant, autosomal recessive, or X-linked traits (Table 137-4). Most are inherited as autosomal dominant traits with a high degree of penetrance.

Hejtmancik has beautifully categorized the different types of genes currently known to be responsible for early-onset cataracts (42). A summary of the major genes and the mode of inheritance of the cataracts they cause may be found in Table 137-4. The genes currently known to play a role in non-syndromic cataract may be broadly grouped into three categories: those that code for crystallins, those that code for membrane/cytoskeleton proteins and those that code for transcription factors.

*Crystallin* gene mutation accounts for about 50% of isolated heritable cataract. Sixty mutations in 98 families have been reported in 10 human crystallin genes.

Adapted from (42).

These typically cause nuclear or lamellar opacities. Most are isolated cataract; however, some are associated with microcornea or myopathy as well (41). Numerous mouse strains with various crystallin genes mutated also demonstrate cataract (41). Crystallins are the predominant protein family found within the lens, with multiple subtypes. One such site is a missense mutation near the  $\alpha$ -crystallin gene, *CRYAA* on chromosome 21q22.3 (59). Investigators identified the cause for a hereditary neuromuscular disorder, desmin-related myopathy, as due to a missense mutation in a highly conserved arginine (R120G) within *CRYAB*, the gene for  $\alpha$ B-crystallin on human chromosome 11q21–23 (60). The  $\alpha$ B-crystallin protein serves as a molecular chaperone and is a member of the small heat shock protein family, found in skeletal and cardiac muscle, in addition to the lens. This point mutation leads to an irregular structure and decreased chaperone function, which may be responsible for the phenotypes of autosomal dominant congenital cataracts and desmin-related myopathy (61,62).

Approximately 35% of isolated heritable cataracts have been found to be associated with mutations in genes for *membrane or cytoskeletal proteins* (41). These genes include connexins, major intrinsic protein (*MIP*), and lens intrinsic membrane (*LIM2*) protein. The connexins code for gap-junction proteins. Two of these genes, *GJA3* and *GJA8*, account for 20% of all isolated hereditary cataracts. Additional genes in this group include *TMEM114*, *CHMP4B*, *ESCRTIII* and *EPH receptor A2*, *BFSP1* and *BFSP2*.

A missense mutation in the *MIP* of the lens, encoded by the gene *MIP* on 12q14, was found to cause autosomal dominant “polymorphic” and lamellar cataracts. The mutations are postulated to interfere with water flow across the lens cell membranes (63). Other genes that may be disrupted and result in cataractogenesis include cytoskeletal proteins (e.g. *BFSP2*).

Mutations in transcription factors (*MIF*, *PITX3*, *HSF4*) often cause other ocular anomalies in addition to

cataract. *HSF4* mutation accounts for about 6% of all familial cataracts (41).

The most extensively studied autosomal dominant cataract is the pulverulent cataract (Figure 137-12). The name is derived from the Latin word *pulvis*, for “powdery” or “dust-like.” Two forms of this cataract have been described. In the zonular pulverulent cataract, dust-like particles are arranged in layers with a clear center in the lens; the lens nucleus is less opacified than the surrounding zone, which contains a high density of fine grained particles (64). This type of cataract was first reported in an extensive study of the Coppock family (34,65). The terms “Coppock” cataract and zonular pulverulent cataract are often used interchangeably in the literature. The Coppock cataract has been linked to mutations in *GJA8*, part of the connexin family, on chromosome 1q21–25 (66). A second site for zonular pulverulent cataracts was found on chromosome 13, near connexin 46 (67). The Coppock-like cataract is due to a mutation in the  $\gamma$ E-crystallin gene (*CRYGE*) on chromosome 2q33–35 (68). This causes increased expression of a truncated protein product and is the first example of a disease process associated with a pseudogene (69). Other genes for the Coppock-like cataract have been found on chromosome 22q11.2–12.2, with a mutation in *CRYBB2* (70) and in *CRYGC* (71). Aculeiform cataracts, Coppock-like cataracts, and polymorphic congenital cataracts (72), all map to 2q33, despite their phenotypic differences (54). The second type of pulverulent cataract described is a central pulverulent type, with similar dust-like opacities, involving only the embryonal nucleus (73) (Figure 137-12). Pulverulent cataracts are typically bilateral and symmetric between two eyes of the same individual. However, both forms of this cataract have been shown to occur within the same family, and even in the two eyes of the same individual (74). In summary, the three groups of genes most likely to be functional candidates in congenital cataract lens mutations include the *CRYG* cluster on chromosome 2 (*CRYGC* and *CRYGD* specifically), the *CRYBB2* on chromosome 22, and *GJA8* gene on chromosome 1 (75).

Variable expression in morphology of pulverulent cataracts in different members of a given family has been described, ranging from faint lens opacities that were difficult to detect, to opacities that obscured the view of the fundus (50); interocular phenotypic variability with seemingly random occurrence of both unilateral and bilateral cataracts in affected individuals in the same pedigree also occurs.

It is likely that the pulverulent cataract has more than one cause, because the genes responsible for this type of cataract have been linked to multiple loci; other studies have failed to demonstrate similar linkage. Isolated congenital cataract transmitted as an autosomal recessive trait is not as common as autosomal dominant; however, it does occur, especially in populations with a high percentage of consanguineous marriages,

**TABLE 137-5**     **Rodent Models of Cataract Mutations**

and it constitutes a significant proportion of hereditary isolated cataracts (52). Mutations have been identified in the *LIM2* gene on 19q13.4 in one family with autosomal recessive pulverulent cataract and a mutation was found in a different consanguineous family with autosomal recessive cataract in the *CRYAA* gene. Other loci previously encountered to be responsible for autosomal recessive cataract include *i* on 6p24, 9q13–22, and 3p (41,42).

Many genes may cause or contribute to the occurrence of congenital cataracts (41,42). To date, genes causing autosomal dominant hereditary cataracts have been mapped to chromosomes 1, 2, and 16 using linkage analysis, and to every other autosome and X using linkage analysis, as well as a variety of other techniques (41,42, <http://cat-map.wustl.edu/>). Autosomal dominant congenital cataracts have been attributed to a missense mutation in the human  $\alpha$ -crystallin gene *CRYAA* on chromosome 21q22.3 (62). Mutations in the *CRYBB2* gene have been shown to cause nuclear cataracts, presumably by altering the folding, and hence the structure of the crystalline protein. The *CRYBB2* gene on chromosome 22 is one of the more important genes in determining the transparency of the lens. As of 2008 there were 39 mapped cataract loci and at least 26 of these locations have a known specific gene and mutation, with more than 100 different cataract mutants identified (42,76,77). A progressive early-onset cataract gene has been mapped to chromosome 17 (78). A locus for autosomal dominant anterior polar cataract has been linked to chromosome 17p, in a four-generation pedigree (79). In addition, autosomal recessive cataracts have been shown to be associated with the small *i* allele (80). Finally, cataracts have been associated with chromosomal translocations, including 3:4, 2:14, and 2:16 and a chromosome 9 inversion (20,81,82). In summary, although distinct morphologic types are identified and classification schemes are available, it is still important to recall that there is much genetic and morphological heterogeneity involved. Because of the genetic complexity of congenital cataracts, fee-for-service genetic testing is not available at this writing.

### 137.3.3 Animal Models

The etiology and pathogenesis of most cataracts is poorly understood. Because the organogenesis and physiology of the lens are essentially similar in various mammals, an understanding of cataract formation in animal models could enhance our knowledge of cataractogenesis in humans. Development of the lens is complex, with many growth factors involved, including fibroblast growth factors and transcription factors (e.g. *PAX6* and others). *PAX6*, in particular, has been identified in the lens vesicle by Western blot analysis as early as 6 weeks gestation (83). Heterozygous mutations in

*PAX6* are known to cause aniridia and microphthalmos, and cataract in some human patients, and homozygous *PAX6* mutations cause severe brain defects as well as congenital absence of the eye. While *PAX6* appears to be a major regulator of eye development, other homeobox genes are also involved, including *PITX3*, *SIX3*, and *OPTX2* (84). The galactose susceptibility of the rat lens has led to its use as a model for galactosemic cataracts (Figure 137-18). Hereditary cataracts have been described in rats, mice, fish, fowl, cattle, dogs (Figure 137-18), the degu, and guinea pig. The various models for inherited congenital cataracts in animals have been reviewed (85). The most commonly studied models are rodents. The main advantages of using rodent mutants include the well-researched genetics of the animals and the comparative ease of breeding large litters. In mice, the models include the Cts strain, Fraser mouse, lens opacity gene (*Lop*) strain, *Lop-2* and *Lop-3* strains, Philly mouse, Nakano mouse, *Nop* strain, Deer mouse, Emory mouse, Swiss Webster strain, Balb/c-net/net mouse, SAM-R/3 strain, and the *Aey2* mutant line, which involves a mutation in the *Crybb2* gene on chromosome 5 (86). Mouse mutants on chromosome 1 (*Cat2*) have mutations in the  $\gamma$ -crystallin gene (87). A mutant on mouse chromosome 3 (*No2*) corresponds with a missense mutation in the human connexin *Cx50* gene. Targeted ablation of *Cx50* in mice resulted in microphthalmos and zonular pulverulent cataracts. *Cx50* is an intercellular channel-forming protein, important for lens transparency as well as lens and overall ocular development (88). The associated human phenotype, the zonular pulverulent cataract, is transmitted in an autosomal dominant fashion, as studied using a missense mutation in the human connexin 50 gene (*P88S*) on chromosome 1q21–25. Only one *P88S* mutant is needed in each gap junction to abolish its proper function (89). The Philly mutant has a mutation in the  $\beta$ -crystallin gene on mouse chromosome 5. Cataracts due to a mutation in *MP10*, on chromosome 10 (*Cat*), are due to a mutation in the *MIP* corresponding to human 12q. The *ak* mutant on mouse

FIGURE 137-18 Cataract rat fed high-galactose diet.

chromosome 19 is due to a genetic defect in homeobox *PITX3*, corresponding to the human chromosome 10q25 (90). The mouse *cat4* mutant on chromosome 8 has anterior polar cataracts, central opacities, and lens–corneal adhesions, analogous to anterior segment ocular dysgenesis (ASOD), which may be due to a mutation in human chromosome 4q (91). A mouse with small lenses and a progressive cataract, which may be a model for age-related cataract, has mutations in *Cryba2* (92), and a mouse homozygous null for *TDRD7* develops cataracts as well as glaucomas (20). The mouse is a valuable model of human cataracts, but it also has an idiosyncrasy of the crystallin lens, which may hold answers in the future: when a mouse becomes very cold and/or when its cornea becomes very dry, the mouse lens rapidly becomes opaque. This opacity reverses quickly with increased body temperature and/or moisture. This reversible opacity of the lens is specific to mice and some other rodents, and even some young kittens.

Rat models include BUdr, ICR, Sprague–Dawley, and Wistar, spontaneously hypertensive rat (SHR), John Rapp inbred strain of Dahl salt-sensitive rat, as well as the WBN/Kob, Royal College of Surgeons (RCS), and Brown-Norway rats (Table 137-6). Because of the ease of making clinical observations in vivo and the subsequent availability of the intact lens for laboratory analyses at different stages of cataract formation, these animals provide excellent models for clinicopathological correlations, for monitoring the natural history of the aging process and metabolic defects, and for investigations on the effects of cataract-modulating agents and drugs, including the prospect of gene therapy (93). The miniature schnauzer (Figure 137-19), in which cataracts are inherited as an autosomal recessive trait, has served as a dog model for recent studies on congenital cataracts and microphthalmia (94).

### 137.3.4 Ocular Disorders Associated with Cataract

Cataracts associated primarily with ocular disorders are summarized in Table 137-7. For practical purposes, the eye is divided into two segments: an anterior segment, consisting of the cornea, angle structures, iris, and lens; and the posterior segment, consisting of the vitreous jelly and the retina. The anterior segment disorders listed in Table 137-7 are aniridia, anterior segment (mesenchymal) dysgenesis, Peter's anomaly, granular dystrophy, microcornea, and microphthalmia (which can also involve the posterior segment). The balance of the disorders is primarily of posterior segment origin. Embryologically, the anterior segment is derived from surface ectoderm and the neural crest. During embryological development of the anterior segment, neural crest cells separate the anterior one-third of the cornea and the lens (both surface ectodermal structures), which it invades in waves to form the posterior two thirds of the cornea, the angle structures, the anterior chamber, and the iris. Interference with this process of separation has been postulated to result in varying degrees of anterior segment abnormalities, such as aniridia (absent iris), which can be either partial (Figure 137-20) or complete; Rieger anomaly (iris hypoplasia and abnormal angle structures); Peters anomaly (central corneal leukoma and cataract) (Figure 137-21); microcornea (small cornea); and microphthalmia (small disorganized eye), all of which have been reported in association with cataracts. A recent report demonstrating a deletion at the *PAX6* locus (a homeobox gene) in a child with Peter's anomaly and heterozygosity in the R26 mutation in the *PAX6* paired box in family members with varying degrees of dominantly inherited anterior segment malformations, including Peter's anomaly, provides strong evidence in support of this theory (94). Many patients with *PAX6*

associated aniridia develop cataracts. Other pedigrees with autosomal dominant cataracts have excluded linkage to *PAX6*, indicating that multiple genes may be significantly involved in anterior segment development (95). *PITX3*, another homeobox gene on chromosome 10q25, was found to be mutated in families with autosomal dominant cataracts and anterior segment mesenchymal dysgenesis (ASMD). *PITX3* is part of the *RIEG/PITX* homeobox gene family, which has been found to be centrally involved in ocular development (2). Other cases of corneal anomalies associated with cataracts include several reports of microcornea and cataract inherited as an autosomal dominant trait (70).

Of the posterior segment disorders listed in Table 137-6, many of which are described in detail elsewhere in this text, retinitis pigmentosa (Figure 137-22) is the most common (1 in 3600 in the general population). Cataracts in this condition, as in other forms of retinal degeneration, typically develop in the third to fourth decade of life and are usually posterior subcapsular in nature (Figures 137-23 and 137-24). These cataracts appear to develop secondary to a cellular response in the vitreous (perhaps inflammatory), not as a primary part of the genetic disorder. Cataracts are also reported in Wagner syndrome, and in hereditary vitreoretinopathies, such as Stickler syndrome. A review of the original pedigree of Wagner syndrome demonstrated that all patients had cataracts by age 45 (96,97), and in most cases had required removal in the previous decade of life. In addition to cataracts and vitreoretinopathy, one such syndrome, which localized to a similar region within chromosome 5q13–14, included ectopia lentis, microphthalmia, persistent hypoplastic primary vitreous, anterior segment dysgenesis, and congenital glaucoma (98). This may be called Wagner plus syndrome and is also known as Cotlier syndrome. Cataracts occur in approximately 50% of patients with Stickler syndrome, or hereditary progressive arthroophthalmopathy, a connective tissue disorder in which the main associated ocular abnormality is retinal detachment, as well as high myopia. In one series, a distinctive wedge and fleck-shaped cataract was

**FIGURE 137-22** Retinal photo showing bone spicule formation in a patient with retinitis pigmentosa.

**FIGURE 137-24** Same cataract shown in Figure 137-3, with diffuse illumination.

found in 43% of patients studied; Seri et al. (99) suggested that these may serve as an early marker for the disease and facilitate early diagnosis. Stickler syndrome patients may be divided into two types. Those with mutations in the *COL2A1* gene tend to have the type 1 vitreous phenotype or *COL11A1* with type 2 vitreous changes. Those with a third mutation, *COL11A2*, have systemic features without any ocular findings (100).

### 137.3.5 Systemic Disorders Associated with Cataract

Cataracts associated with autosomal syndromic genetic syndromes overlap somewhat with cataracts associated with metabolic disorders (which are predominantly recessive); some of the more important disorders in both groups are listed together in Table 137-7.

Cataracts are a feature of several disorders, which are primarily skeletal in nature: chondrodysplasia punctata, pseudohypoparathyroidism, and Stickler syndrome (discussed previously), with which they are commonly associated; and Kniest dysplasia, Marfan syndrome, homocystinuria, and Majewski syndrome with which they are more rarely associated.

Chondrodysplasia punctata (Conradi–Hunermann syndrome) is characterized by asymmetric limb shortness, early punctate mineralization, and large skin pores resembling orange peel, as well as sparse coarse hair. Both dominant and X-linked dominant cases (lethal in males) have been described. Cataracts occur in up to 17% of patients. A recessive form (rhizomelic type) has also been described, characterized by short humeri and femora, coronal cleft in vertebrae, and punctate epiphyseal mineralization. Cataracts occur in up to 72% of patients in this group.

Pseudohypoparathyroidism (Seabright–Albright syndrome) is a defect in calcium phosphate metabolism. Both short stature and cataracts are related to the hypocalcemia that occurs in these patients. Other abnormalities include subcutaneous calcifications and brachydactyly. Because of a defect of kidney and skeletal adenylcyclase, serum calcium is low and serum phosphate elevated in spite of excessive secretion of parathyroid hormone.

In Hallermann–Streiff syndrome, or oculomandibulodyscephaly with hypotrichosis syndrome, cataracts occur in 94% of cases and microphthalmia occurs in 80% of cases. Other features comprising this syndrome are a small pinched or parrot-like nose, and hypotrichosis. Other occasional ocular abnormalities include blue sclera, nystagmus, strabismus, optic disc colobomata, glaucoma, and retinal pigment alterations.

Cataracts commonly occur in association with several skin diseases, including Werner syndrome, anhidrotic ectodermal dysplasia, hereditary ichthyosis, Rothmund–Thomson syndrome, and incontinentia pigmenti. Rothmund–Thomson syndrome, which includes poikiloderma, growth deficiency, premature aging, and predisposition to some malignancies, in addition to bilateral

cataracts, is attributed to mutations in the RECQL4 heliase gene (101,102). An important congenital malformation in incontinentia pigmenti is retinal dysplasia, but juvenile cataracts occur commonly in this disorder. Other ocular abnormalities include corneal opacities, strabismus, optic atrophy, uveitis, chorioretinitis, microphthalmos, nystagmus, and nasolacrimal duct obstruction.

Cataracts occur in many neurological syndromes. Congenital cataracts and microcornea are found in the autosomal recessive congenital cataract facial dysmorphism neuropathy (CCFDN) syndrome, which includes motor neuropathy, and moderate mental retardation with occasional pyramidal signs (103). A syndrome involving bilateral cataracts, spastic paraparesis with amyotrophy, and gastroesophageal reflux with persistent vomiting was mapped to chromosome 10q23.3–q24.2 (99).

Myotonic dystrophy is a dominant muscular dystrophy with a distinctive type of cataract. Typical lens changes occur in all patients in the second decade of life as multiple spots of opacity, with colored crystals localized in the anterior and posterior subcapsular layers in the form of a thin band, later progressing to maturity (104). Although characteristic opacities seen only by slit-lamp examination in the past constituted a principal method of presymptomatic detection of gene carriers, the discovery that the dystrophy mutation is an unstable DNA sequence, composed of varying numbers of CTG triplet repeats in the *DMPK* gene, allows for a specific molecular test for this disorder (105). Lens epithelial cells from patients with myotonic dystrophy were found to have decreased amounts of myotonic dystrophy protein kinase gene and decreased epithelial cell densities, perhaps leading to the iridescent opacities or PSCs observed in this syndrome (106). Experiments demonstrate that mice with deficiency in the *Six5* gene adjacent to the *DPMK* gene develop cataracts, and that the rate and severity of cataract formation is inversely related to the amount of *Six5* present (107,108). Congenital nuclear cataracts, with later developing anterior subcapsular cataracts, were reported in a patient with mild Becker muscular dystrophy due to a giant dystrophin deletion, similar to that found in the *mdx* mouse (109). It must be noted that the iridescent opacities characteristic of MD cataracts may also be found in the general population (110).

Neurofibromatosis 2 is an autosomal dominant disorder characterized by development of bilateral vestibular schwannomas and central nervous system (CNS) tumors (111). Its incidence is approximately 1 per 40,000 live births. In a recent survey of 49 patients with neurofibromatosis type 2, cataracts were found in 69% of patients. Cataracts can be the initial mode of presentation. The types of cataracts found in neurofibromatosis type 2 were posterior subcapsular or capsular (26.5%), cortical (26.5%), mixed (14.2%), and Mittendorf dots (8.2%) (112). Cataracts have also been reported in tuberous

sclerosis, another of the autosomal dominant inherited phakomatoses (113). Two rare dominant disorders in which cataracts also associated are nail patella syndrome and the oculodentodigital syndrome.

Several renal diseases have cataracts as part of their presentation. These include Lowe syndrome, Hunter-Jurenko syndrome, renal-dysplasia-cataract-blindness syndrome, Senior-Loken syndrome, Alport syndrome, Fabry disease, and Zellweger syndrome, as well as an autosomal recessive syndrome with immune complex glomerulonephritis and ophthalmic abnormalities (114).

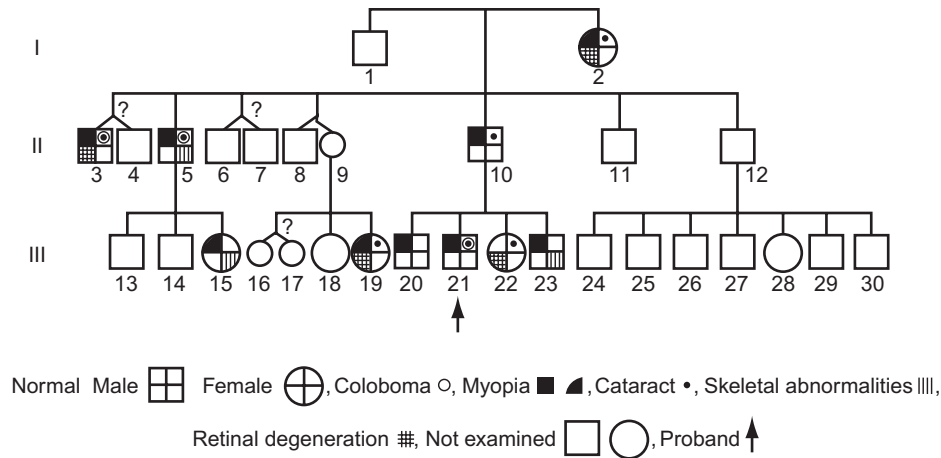

The most common in this group of diseases is Lowe syndrome, an oculocerebrorenal syndrome, with X-linked recessive inheritance. Affected hemizygous males have mental retardation, renal aminoaciduria, and ocular abnormalities, including congenital cataracts. Other ocular anomalies include glaucoma with dysgenic angles, pupillary abnormalities, and corneal keloids. Female carriers of Lowe disease have characteristic punctate spoke-like opacities in the lens cortex (115). The Lyon effect has been invoked in this disorder, with all lens fibers involved in affected hemizygotes, and only a proportion of fibers affected in female carriers, resulting in the characteristic spoke-like opacities. Since the gene for Lowe syndrome has been mapped on the X chromosome, suspected carriers can now be confirmed by molecular genetic studies (116). Different mutations within the *OCRL-1* gene may lead to different phenotypes (117). Lowe syndrome is a ciliopathy.

In Fabry disease, cataracts appear later in life. The female carrier has characteristic spoke-like lens opacities (Figure 137-25). Other ocular findings include vascular lesions of the conjunctiva, whorl-like opacities of the cornea, and vascular lesions of the retina (118). In Alport syndrome, described earlier, anterior lenticonus

**FIGURE 137-25** Spoke-like cataract in a patient with Fabry disease.

**FIGURE 137-26** Family pedigree showing autosomal dominant inheritance in Cotlier syndrome.

is the more prominent finding, with cataracts occurring only rarely.

Zellweger syndrome, or cerebrohepatorenal syndrome, is a multisystem disorder resulting from peroxisome malfunction, abnormal development of the skull, face, ear, hands, and feet, as well as some mental retardation, hepatic interstitial fibrosis, renal and cortical cysts, and ocular anomalies. Zonular cataracts are noted in association with this syndrome. Heterozygote carriers have curvilinear lens opacities, which can be a useful diagnostic aid if seen in a parent with a child who has the Zellweger facies and who is suspected of having the disorder. Other ocular abnormalities include cloudy cornea, optic atrophy, and retinal dystrophy with an extinct electroretinogram (ERG) (119).

Several other systemic diseases have retinal dystrophy and cataracts as part of the ocular manifestations. These include Refsum disease, Usher syndrome, Kearns–Sayre syndrome, gyrate atrophy, choroideremia, Bardet–Biedl syndrome, Cockayne syndrome, (see Chapter 147) and Cotlier syndrome. Cataracts have been identified in both early onset and classic Cockayne syndrome (120). Cotlier syndrome is an autosomal dominant disorder (Figure 137-26) with dense, punctate infantile cataracts (Figure 137-27), lens dislocation, retinal degeneration of the pigmentary perivascular type (Figure 137-28), retinal detachment, and skeletal Marfan-like dysmorphic features.

Cataracts associated with microcephaly and mental retardation are seen in Torsten Sjögren syndrome, Marinesco–Sjögren syndrome, Crome syndrome, Martosolf syndrome, CAMFAK syndrome, Lenz dysplasia, Smith–Lemli–Opitz syndrome, and Menkes syndrome. Micro syndrome encompasses autosomal recessive microcephaly, microcornea, congenital cataract, mental retardation, agenesis of the corpus callosum, retinal and optic atrophy, and hypogenitalism (121,122).

Marinesco–Sjögren syndrome consists of congenital cataract, mental retardation, and cerebellar ataxia (123) with lysosomal storage. In addition to cataract,

**FIGURE 137-27** Punctate infantile cataract seen in Cotlier syndrome.

Lenz dysplasia is associated with microcephaly and mental retardation, colobomatous microphthalmos, nystagmus, esotropia, short stature, kyphoscoliosis, anteverted simple pinnae, and dental anomalies (124). CAMFAK syndrome, an autosomal recessive trait, is an acronym for cataract, microcephaly, failure to thrive, and kyphosis (125). Nance–Horan syndrome is an X-linked disorder which may cause mental retardation, and which includes dental defects and severe congenital cataracts. Different mutations in the NHS gene on Xp have also been found to cause isolated

**FIGURE 137-28** Retinal photo showing perivascular pigmentary retinal degeneration in Cotlier syndrome.

congenital cataracts (42). Hyperferritinemia-cataract syndrome is an autosomal dominant disorder in which hyperferritinemia unassociated with iron overload leads to progressive cataract. L ferritin builds up in the lens (42).

### 137.3.6 Cataracts Associated with Biochemical Abnormalities

Cataracts associated primarily with metabolic disorders are found in disorders of cholesterol synthesis, galactosemia, mannosidosis, neuraminidase deficiency, phenylketonuria, and Wilson disease. Inherited defects in enzymes of cholesterol metabolism are associated with cataracts. The basis of this relationship apparently lies in the need of the lens to satisfy its sustained requirement for cholesterol by onsite synthesis; impaired synthesis of cholesterol can lead to alteration of the lens membrane structure. Lens membrane contains the highest cholesterol content of any known membrane. Smith–Lemli–Opitz syndrome, mevalonic aciduria (MAU), and cerebrotendinous xanthomatosis all involve mutations in enzymes of cholesterol metabolism; affected patients can develop cataracts (126). Cataracts have also been noted to occur in cystic fibrosis, with an increase noted as digestive function declines (127).

Smith–Lemli–Opitz syndrome is expressed in infancy by microcephaly, poor growth, dysmorphic features, genital and limb abnormalities, and mental retardation. Cataracts can also accompany the condition (128) (Figure 137-29). Patients with infantile cataract associated with pseudohermaphroditism should be tested for this

**FIGURE 137-29** Cataract in a patient with Smith–Lemli–Opitz syndrome.

disorder, as these findings typically occur together in this disorder. A buildup of 7-dehydrocholesterol and its metabolites largely replacing cholesterol occurs, resulting from a defective enzyme  $3\beta$ -hydroxycholesterol 7-reductase, which causes a block in the reduction of the double bonds between C-7 and C-8 in 7-dehydrocholesterol and in a precursor, desmosterol (129).

MAU is a rare autosomal recessive condition involving marked reduction in mevalonate kinase activity. It is expressed in infancy and carries a high rate of mortality. A defective form of the enzyme can result from a single base substitution in the coding region of this single-copy gene. The condition is characterized by developmental delay, dysmorphic features, hepatosplenomegaly, and progressive atrophy of the brain. The more severely affected individuals have cataracts. Serum and urinary levels of mevalonic acid can increase by more than 10,000-fold. The pathology, including the cataracts, could be a consequence of either reduced synthesis of cholesterol and its essential nonsterol precursors or more likely to direct toxicity from the accumulated mevalonic acid (126).

Cataracts plus Achilles tendon xanthomas before age 30 is the hallmark of cerebrotendinous xanthomatosis (130). The types of cataracts vary and are generally bilateral, with other ocular abnormalities, including optic atrophy being possible. Other features may include mental retardation and neurological abnormalities may also accompany this condition. Cerebrotendinous xanthomatosis can present in both children and adults, with 86% of affected patients having cataracts. This condition involves the accumulation of an unusual sterol, cholestanol in body sites, including the lens. It arises from a block in hepatic synthesis of bile acids due to a defect in the mitochondrial 27-hydroxylase required for oxidation of the cholesterol side chain.

Elevated serum ferritin and bilateral cataract formation have been identified in the hereditary hyperferritinemia-cataract syndrome (HHCR) which is autosomal dominant. The lens changes are dense

sutural and cortical opacities formed from amorphous mildly eosinophilic crystalline deposits (131). Affected individuals have normal serum iron and transferrin, but high serum ferritin. This elevation may be useful as a screening test for patients at high risk for this disease. It is interesting that the LIM2 structural gene is on human chromosome 19q13.4, with a protein product of 19.7 kD, which is similar to the size of the ferritin L-subunit (132).

Galactosemia is a disorder caused by a deficiency of any one of three possible enzymes involved in the metabolism of galactose; galactokinase, transferase, or epimerase. Any single deficient enzyme can result in cataract through the accumulation of galactitol in the lens. It is a rare cause of congenital cataract but should be considered high on the list of differential diagnosis because of the salutary effect of early dietary therapy. The metabolism of galactose into glucose involves three steps, each assisted by an enzyme:

1. galactose + ATP to galactose-1-P (assisted by galactokinase);
2. galactose-1-P + UDP glucose to glucose-1-P (mediated by galactose-1-phosphate uridylyltransferase; and
3. UDP-galactose to UDP glucose (mediated by UDP GAL-4-epimerase).

Deficiency in the enzyme galactokinase causes galactokinase deficiency and an absence of galactose-1-phosphate uridylyltransferase causes classic galactosemia in homozygotes. Both are autosomal recessive diseases. In both diseases, the accumulation of galactitol, a metabolite of galactose, causes the development of infantile cataracts in most untreated patients. Deficiency of the third epimerase enzyme was discovered incidentally in the evaluation of children screened for galactosemia. There are two variants of this disorder: a benign one without signs of galactosemia, and a more severe variant in which cataract formation has been reported.

In galactosemia, other abnormalities beside cataracts include nutritional failure, mental retardation, hepatosplenomegaly, and cirrhosis. In galactokinase deficiency, cataracts may be the sole manifestation in homozygotes. The morphological structure of the cataract in both diseases, if untreated, is similar. Initially a zone of lens becomes opacified. This can be nuclear, sutural, lamellar, posterior, cortical, or any combination of the above; the opacification ultimately progresses to mature cataract (Figure 137-30). The cataract is usually diagnosed in the first year of life, but an incomplete cataract may go unnoticed until the second or third decade of life.

In neuraminidase deficiency (sialidosis and galactosialidosis), ocular abnormalities include cherry-red spots in the macula, optic atrophy, corneal opacities, and lenticular opacities. There are two types, with cataracts more common in type I and corneal opacities found more commonly in type II.

**FIGURE 137-30** Cataract in a patient with galactosemia.

**FIGURE 137-31** Artist impression of cataract noted in a patient with mannosidosis. (Courtesy of A. Linn Murphree, MD, Children's Hospital of Los Angeles.)

Other rare inborn errors of metabolism in which infantile cataracts have been reported are mannosidosis type I (Figure 137-31) and type II. Wilson's disease (hepatolenticular degeneration) is transmitted as an autosomal recessive trait and is characterized by juvenile cirrhosis of the liver and degeneration of the lentiform nucleus of the brain. It is caused by disturbed copper metabolism, with faulty or decreased synthesis of ceruloplasmin. Free serum copper is increased and copper deposits are not only found in the liver and brain stem but also in the eye. The cornea and lens accumulate copper, the latter in the form of a characteristic sunflower cataract (Figure 137-32), a yellowish star-like anterior subcapsular discoloration (133). Other rare case reports of congenital

cataracts have been reported in deranged proteoglycan (i.e. acid mucopolysaccharide–xylose–protein complex) metabolism with released xylose in the blood and urine and xylitol in the lens. Bilateral infantile nuclear sclerotic cataracts were described in a patient with a deficiency of complex I, a mitochondrial electron transport chain enzyme, which causes severe lactic acidosis and neurological dysfunction in the newborn (134). Sorbitol dehydrogenase deficiency may also cause congenital cataracts.

Cataracts associated with chromosomal anomalies are listed in Table 137-8. Of these the only morphologically characteristic cataract is the one found in Down syndrome, characterized by coronary and stellate cataracts in infancy or adolescence (Figure 137-33).

**FIGURE 137-33** Coronary cataract with stellate opacities typically seen in patients with Down syndrome between two eyes of the same individual. However, both forms of this cataract have been shown to occur within the same family, and even in the two eyes of the same individual (Girardet, 1943) (89).

### 137.4 THERAPY

Accurate diagnosis is the first step in the management of congenital lens anomalies. A rational approach to congenital cataract is outlined in Table 137-3. For congenital cataracts that interfere with vision, surgery is the only option. The one exception is the cataract in galactosemia, which may be reversed by dietary control. Although galactosemia is rare, the clinician should always have a high index of suspicion for this disorder. Once the diagnosis of galactosemia is confirmed, careful dietary management is required immediately, entailing the exclusion of all milk and milk-containing foods. Food containing galactose, such as organ meats, should also be avoided.

Management of congenital cataracts involves observation over time by a pediatric ophthalmologist if the opacities are minimal and do not interfere with vision. Specialized tests are needed to determine whether this is the case in young infants who cannot yet communicate. Opacities in the lens (cataracts) may result in deficient cell development of the visual cortex or other CNS centers such as the lateral geniculate body. The surgical removal of dense cataracts in infants before the age of 3 months has been advocated to prevent irreversible CNS damage. Studies have shown that only children who have a clear visual axis with optical correction in place before 4 months of age have a chance for normal vision. Aphakia (or lack of lens) results from surgical removal of cataracts. To correct for the optical strength of the lens, intraocular lenses, contact lenses, or glasses must be provided (135).

In patients with unilateral cataracts, amblyopia or poor vision due to lack of brain or retinal use can be prevented by a protocol of monitored occlusion of the sound eye to stimulate vision in the aphakic eye in

patients with unilateral cataracts. In addition, cataracts removed in infants with small eyes (microphthalmos) or large eyes (myopia) must be treated for the additional refractive error to prevent amblyopia (136). Corneal curvature problems (astigmatism) are another cause for amblyopia after cataract removal (137).

The surgical removal of bilateral cataracts in infants yield good visual results in the majority of cases (136), with intervention before 3 months of age usually yielding better results (139,140). Very early surgery (less than 2 weeks of age) has recently been reported to be associated with higher risk of developing glaucoma. Timing is still being investigated, but surgery performed between 2 and 6 weeks of age may offer the best visual results with the lowest increased risk of glaucoma. Follow-up of operated aphakic infants is paramount, as secondary glaucoma develops in many patients (141), and amblyopia remains a formidable obstacle following cataract surgery. Furthermore, the correction of aphakia with glasses or contact lenses requires continuous supervision as lenses are lost or glasses are scratched. Although controversy exists regarding the youngest age indicated for intraocular lens implantation, intraocular lenses are being increasingly implanted in patients with congenital cataracts. Results from a multicenter trial, the Infant Aphakia Treatment Study, which compared using contact lenses vs primary intraocular lenses in patients with congenital cataracts, found no difference in visual outcomes at 1 year of age, but the primary intraocular lens group required significantly more reoperations over the study period (142). Intraocular lens implantation after 2 years of age has become the standard of care for most practitioners in the USA. In the final analysis, the success of cataract surgery in infants depends on a close cooperation among physicians in various specialties, including pediatrics, neurology, genetics, and ophthalmology, and with their parents and caretakers who must do rigorous amblyopia treatment at least to the age of 9 years. Even with excellent care, some eyes will not have a good outcome, usually due to other ocular anomalies. Many of these might be predicted by the genetic cause of the cataract, however routine fee-for-service testing for isolated congenital cataracts is not available at the time of this writing. Some testing is available for cataracts which are part of a syndrome, such as PAX6. Availability of genetic tests, frequently updated, can be found online at [www.genetests.org](http://www.genetests.org). An excellent resource for understanding hereditary cataracts is the site *Cat-Map*. This site lists all currently known cataract genes and loci by chromosomes. It can be accessed at <http://cat-map.wustl.edu/>.

### Biography

**Arlene V Drack, MD** is a clinician scientist specializing in juvenile inherited eye diseases. She is the inaugural Ronald V Keech Associate Professor in Pediatric Ophthalmic Genetics at the University of Iowa Department of Ophthalmology and Visual Sciences. Her research focuses on inherited eye diseases that affect children, particularly in the development of novel treatments. She codirects both the clinical and rodent electroretinogram services at the University of Iowa. Her clinical practice includes the full scope of pediatric ophthalmology and strabismus, in addition to running specialized genetic eye disease clinics.

### 138.1 INTRODUCTION

Inherited diseases of the retina and choroid cause significant visual morbidity with a number of them presenting during early childhood. There are over 1500 inherited diseases in which the term retina or choroid is mentioned in a search on the online Mendelian inheritance in man database ([www.omim.org](http://www.omim.org)). There are 184 retinal disease-causing genes identified so far, with a number of loci at which genes have yet to be identified (Retnet). With the rapid advances of technology in molecular genetics, gene discovery is accelerating. Whole exome and next generation sequencing has lead to the identification of several additional genes such as *GPR179*, *GNPTG*, *KIF11*, *MAK*, *HARS*, *LZTFL1*, *PLA2G5*, *TMEM237*, *C8ORF37* within the past 2 years (Table 138-1). However, as our ability for high through-put sequencing and identification of sequence variations is increasing, so are the challenges of translating this information from bench to the clinic—to individuals and families. Some laboratories in the United States are currently offering molecular genetic testing for a number of retinal and choroidal disease-causing genes as panels. A number of changes that can be missense, nonsense, splice altering variants, gene inactivating promoter mutations and copy number variations may be identified and can be disease-causing or benign variants. Given the difficulty in accurately determining the sequence variations as mutations or polymorphisms, and the increasing number of variants of unknown significance, the clinical exam remains very important. The classical diagnostic approach to retinal dystrophy patients is to correlate the fundus pattern (morphological appearance) and inheritance pattern with the results of electrophysiological and psychophysical tests such as the electroretinogram (ERG), electrooculogram (EOG), dark adaptation, and visual field test (1). These results are compared to the patterns seen in established

disease entities for the most accurate diagnosis. Frequently, the clinical appearance and test results clearly establish the clinical diagnosis, but because many retinal diseases have similar fundus appearances or nonspecific abnormalities, it may be necessary to observe the clinical course of the disease over many years and examine other affected family members in order to finalize the diagnosis. Hereditary diseases of the eye, with rare exceptions, have bilateral symmetrical involvement. When unilateral ocular disease is seen, other causes, such as birth defect, intrauterine or antenatal infection, trauma to the eye, and inflammatory diseases should be considered first, before giving the diagnosis of a hereditary etiology. If the asymmetry is in visual acuity without tissue changes, amblyopia may be the reason. Occasionally a patient will be seen with uniocular disease, which becomes bilateral after several years and, presumably, the uninvolved eye was in a subclinical state on the initial examination.

The genetic and phenotypic heterogeneity in retinal diseases are well established. The pleiotropy of single disease-causing gene, has been seen in a number of different retinal genes including *RDS*-peripherin2 where macular dystrophy, adult vitelliform lesions, retinitis pigmentosa (RP) like phenotype, central areolar choroidal dystrophy and fleck retinal phenotypes have been seen (2), *CRX* mutations where autosomal dominant and recessive Leber congenital amaurosis and cone-rod dystrophy have been observed and *ABCA4* mutations resulting in Stargardt's disease, cone-rod dystrophy and RP (3). Given this complexity, the clinical laboratories, ophthalmologists, geneticists and genetic counselors have to work together as a team to provide the most accurate diagnosis, one that is consistent clinically and molecularly, and to facilitate personalized therapeutic options. We will discuss the genetics and clinical presentation of a number of isolated retinal and choroidal diseases in this chapter.

## 138.2 INHERITANCE PATTERNS AND MOLECULAR GENETICS

Most hereditary retinopathies follow conventional Mendelian patterns of inheritance; that is, autosomal dominant, autosomal recessive or X-linked recessive. However, more complex patterns are also known, such as X-linked recessive with expression in female “carriers” (4); digenic inheritance, which results from the sum of independent mutations, such as in *peripherin2/RDS* and *ROM1*; and mitochondrial mutations, which follow a maternal pattern of inheritance (Tables 138-1). A family in which expression follows an X-linked dominant pattern has been identified in which males are severely affected from early age, while females have a clear RP-like progression during adult years (4). Furthermore, many cases present as isolated or sporadic, that is, without other known affected relatives, so the mode of inheritance may be unclear.

Exceptional progress has been made in identifying genes and mutations causing inherited retinal and choroidal degenerations during the past decade. To date, 184 genes have been identified (the underlying gene and mutations are known) and an additional 41 loci mapped by linkage methods (assigned to a chromosomal site) (Table 138-1) (Retnet). This information has helped elucidate the various patterns of inheritance, but it has also demonstrated the extraordinary complexity of these disorders.

Based on these developments, inherited retinopathies are best characterized by the word “heterogeneity”—perhaps more so than for any other class of hereditary disease. There are three applicable types of heterogeneity.

First, there is genetic heterogeneity; that is, different genes can cause apparently similar conditions. For example, mutations in at least 22 different genes can cause autosomal dominant RP, some of which also cause autosomal recessive RP (Table 138-1). Although the clinical phenotypes caused by these 22 genes are similar, the biochemical pathways of the known proteins are distinct (5). One plausible reason that different pathogenic mechanisms might lead to similar clinical consequences is that in all cases studied to date, the end stage of retinal degeneration involves photoreceptor apoptosis (6).

Second, there is allelic heterogeneity; that is, different mutations in the same gene can cause different retinal diseases. For example, different mutations in *peripherin/RDS* can cause pattern dystrophies, adRP like phenotype, dominant macular dystrophy, or dominant pan-retinal degeneration (2). Also, different mutations in rhodopsin can cause adRP, dominant congenital stationary night blindness, or recessive RP (7). One reason for this variety of allelic phenotypes is that most proteins do not have just one “function,” but rather, multiple functional properties which reside in different portions of the molecule. Thus, *peripherin/RDS* is expressed in both rods and cones, but expression of *ROM1*, which binds to *RDS*, is limited to rods, so the pathology of some *RDS* mutations will be rod-specific, others cone-specific, and still others both.

Finally, there is clinical heterogeneity; that is, clinically distinct phenotypes caused by the same mutation, even within the same family. In general, a hallmark of dominant diseases with delayed onset is significant variation in age-of-onset and severity. This is particularly true

of dominant retinopathies, such as adRP. For example, different individuals with the Arg677Ter mutation in the RP1 gene can have early-onset adRP, late-onset adRP, or an apparent lack of clinical consequences; that is, a “skipped generation” (8). More strikingly, a splice site mutation in peripherin/RDS manifests as adRP, pattern dystrophies that progress to appear as atrophic macular dystrophies or dominant chorio-retinal disease (Figure 138-1a, b). A reasonable explanation for clinical heterogeneity is the modifying effects of environmental and additional genetic factors. However, environmental factors have not been identified in most cases (with the exception of sunlight exposure), and evidence for genetic factors is only suggestive (8).

As a consequence of this heterogeneity, a thorough clinical evaluation and a complete family history, including pedigree construction, are necessary to identify the mode of inheritance and underlying mutation, but are often not sufficient. On many occasions the ultimate diagnosis depends on the results of genetic testing. The use of newer technologies such as next generation sequencing has resulted in the identification of disease-causing mutations in adRP to 65% (9). With newer gene and mutation discoveries, this is likely to increase.

### 138.2.1 Incomplete Penetrance

Incomplete penetrance in obligate cases of dominant RP has been documented on occasions in which the patient has no or very minimal retinal findings compared to affected age-matched relatives. The lack of obvious disease in an obligate carrier of the mutant dominant gene can be a source of confusion when first encountered, since it may initially mislead genetic counseling and cause errors in linkage analysis studies. Many of these patients when re-examined and tested a number of years after the initial visit will demonstrate signs of disease, but they are never as severely affected as fully penetrant relatives. The reason for the incomplete penetrance is not understood, but is presumed to be because of secondary gene interaction. The most striking example of a modifying factor is seen with PRPF31, mutations which cause the RP11 form of autosomal dominant RP. At least 10% of individuals carrying a disease-causing mutation in PRPF31 show no disease symptoms late in life, though other family members may be severely affected. Evidence suggests that the unaffected copy on the homologous chromosome can play a protective role in some cases (10). This is one of the best documented examples of secondary genetic effects controlling the consequences of primary mutations.

### 138.2.2 Variable Expressivity

Because the classification of these diseases relies heavily on the morphological appearance of the retina, the diagnosis may be confused by phenotypic variability. This

**FIGURE 138-1** a, b. Lipofuscin deposits in the macular region consistent with butterfly pattern dystrophy progressing over 10 years to cause atrophic lesion in the macula as in b.

can be seen as heterogeneity and variable expressivity of findings in autosomal dominant families, or instances of secondary expression, in which additional pathological conditions occur in a few patients when the majority of the patients with the same retinal degeneration do not have the finding. This is illustrated by cases of RP in which there is also Coats’ disease or retinal neovascularization. This phenomenon occurs rarely in RP and appears to represent one way that the retina responds in the degenerative process. The Coats’ reaction is more commonly seen in patients with RP12 due to mutations in the CRB1 gene where up to 30% of patients will develop this condition in one eye (11).

Variable expressivity that could be mistakenly called a new type of RP was exemplified in two Navajo sisters with autosomal recessive RP who were found to have unocular neovascularization; but on inspection of 40 other autosomal recessive Navajo RP patients, no other cases of retinal neovascularization were found. Presumably factors other than primary gene expression were responsible for the neovascularization in the two sisters. Another diagnostic problem are patients with distinctive patterns of retinal degeneration in which there are potentially multiple genetic etiologies for the fundus

appearance; as an example, white spots in the retina seen in retinitis punctata albescens, fundus albipunctatus, fundus flavimaculatus (Stargardt's disease), Malattia Leventinese, and vitamin A deficiency can look very similar on examination. Fortunately, the correct diagnosis can be confirmed by clinical electrophysiological and visual field testing and/or blood/DNA testing, as the gene has been found for all these entities. Another distinctive pattern that is presumably associated with multiple etiologies is a disorder called pigmented paravenous retinochoroidal atrophy (Figure 138-2) these patients demonstrate

**FIGURE 138-2** Pigmented paravenous retinochoroidal atrophy is a distinctive pigmentary degenerative pattern occurring next to retinal veins and sometimes caused by heterozygous mutations in *CRB1*.

pigmentary degenerative changes next to retinal veins. Some cases are progressively like RP, but most have a stable disorder. In the past, paravenous pigmentary patients have been regarded as having a distinct form of RP. However, this degenerative pattern has been documented to occur in many diseases; these include Wagner's and Stickler's vitreoretinal degeneration, rod-cone and cone-rod degenerations, as well as in sarcoidosis; the retinal degenerations in these cases are not likely to be due to the same etiology, although similar pathophysiological mechanisms may be occurring next to the retinal veins in these different disorders. In one family, heterozygous val162-to-met mutation in the *CRB1* gene has been reported as the causative mutation in six affected family members (12).

### 138.2.3 Visual Electrophysiological Testing

There are a number of tests that are useful in classifying the hereditary retinal and choroidal degenerations, which will be mentioned in summary fashion here since there are extensive reviews in other sources (Table 138-2) (1). The ERG is an evoked response in which a signal generated by the retina in response to a flash of light is recorded (after topical anesthesia) by a contact lens or foil electrode on the surface of the eye. Eyelid skin electrodes are occasionally employed in children but do not give as good quality tracings and should be avoided if possible. Careful standardization of test conditions is essential in order to obtain interpretable results. A kinetic (Goldmann) visual field is often needed to correctly interpret the results of the ERG testing and to evaluate visual function. When

**TABLE 138-2 Typical Electrophysiological Changes Seen in Retinal Diseases**

ERG Change	Disease (or Condition)
Nonrecordable ERG	Leber amaurosis congenita; retinal aplasia; RP; total retinal detachment
Abnormal or nonrecordable photopic ERG often mild rod ERG abnormalities	Cone degenerations-AD, AR; rarely, early RP which is progressive; Achromatopsia; X-linked blue monochrome monochromatism; X-linked cone dystrophy with tapetal-like sheen
Nonrecordable rod ERG, abnormal bright-flash dark-adapted ERG, normal to near normal photopic ERG	Congenital stationary night blindness; rarely, early RP which is progressive
Barely or nonrecordable scotopic ERG, abnormal photopic b-wave ERG	Rod-cone degenerations, typical RP; Leber's congenital amaurosis (juvenile form); choroideremia; chorioretinitis (variable); secondary RP including some storage diseases; progressive RPA
Abnormal cone and rod b-wave amplitudes, cones are relatively more affected than rods	Cone-rod degenerations, AD, AR, XLR; postinflammation (e.g. luetic chorioretinitis, which may also have a rod-cone pattern)
Negative waveforms: In the dark-adapted bright flash ERG the a-wave is normal to attenuated, but the b-wave does not return to the isoelectric point	X-linked retinoschisis; congenital stationary night blindness; enhanced blue-cone syndrome (Goldmann Favre disease); some autoimmune retinopathies
Nonspecific abnormalities	Metallic foreign bodies; chorioretinitis (acute or old); vasculitis/diabetic retinopathy; low serum taurine; early panretinal degeneration; partial retinal vascular occlusion

Standardized ERG testing isolates cone and rod function, as well as tests both rods and cones together. Comparison of each component against the others gives functional data that helps in arriving at the clinical diagnosis.

<sup>a</sup>X-linked rod-cone and cone-rod ERG patterns have been found within the same RP pedigree and appear to represent variable expressivity; however, these electrophysiological patterns have otherwise been consistent within pedigrees of autosomal dominant and recessive RP patients.

the test is performed in the light-adapted state, the test is called a photopic ERG and measures the cone system. The rods in the light-adapted state are bleached out, and do not respond to the light stimulus. Cone function also can be measured with a flickering stimulus, since rods do not respond over 20 cycles per second. After the patient is dark-adapted for at least 30 min, the test is repeated with a dim flash of light below cone threshold. This stimulus evokes a rod-isolated response. A mixed cone and rod response, testing both photoreceptor systems, is often performed with a bright flash in the dark-adapted state. The ERG is a mass response of the photoreceptors and does not correlate with visual acuity, which is a function of macular health. The macula only contributes a small fraction of the total ERG response.

As a general principle, it is important to separately test the cone and rod systems in a standardized fashion, since comparison of the relative changes is used to support or make clinical diagnoses. The first electroretinographic response to appear is a negative or downgoing waveform called the “a-wave,” representing the response of the receptor layer. The second waveform to appear is a positive upgoing or “b-wave” that is derived from bipolar and Mueller cells in the middle retina. Certain components of the ERG are lost or altered depending on the disease and severity of involvement. By comparing the cone-isolated, rod-isolated, and mixed cone and rod responses, diagnostic patterns are commonly seen in hereditary retinal disease states and are presented in [Table 138-2](#). A multifocal ERG has been developed for testing foveal function independent of the mass response type ERG. The Pattern ERG uses a check board pattern stimulus in which the total luminance never changes even though the checkerboard pattern changes, and this has been shown to measure function of inner retinal neuronal cells ([13](#)).

The EOG measures the standing potential that exists between the front and back of the eye, and is generated by the retinal pigment epithelial (RPE) layer, a continuous single cell layer under the retina. The EOG is altered in diseases affecting the RPE. The test is performed by placing skin electrodes medial and lateral to each eye. The patient looks alternately between two points 20° apart for periods of time in the light and then in the dark. The amplitudes of the response are quantified and expressed as a ratio, with the largest light-adapted value divided by the smallest dark-adapted value and the result multiplied by 100. This percentage value is called the Arden ratio. One hundred percent (100%) would indicate no response, and would be typical of advanced RP. Different normal values may be encountered depending on the measuring technique of the individual laboratory performing the test. The EOG is important for evaluating an individual suspected of having Best’s vitelliruptive degeneration, an autosomal dominant disorder in which the ERG is normal and the EOG is abnormal. Patients with the Best’s disease

gene and no fundus changes can be identified by the EOG. Typical normal values for the EOG are 180% or greater. The values are age-related and are altered in many retinal degenerative disorders.

The dark adaptation test measures the threshold of sensitivity of the retina to a small spot of light after the patient is placed in the dark and typically is measured over a 40 min period. The curve generated is bimodal, measuring the cone’s sensitivity first; at about 9 min the rods become desaturated and become progressively more sensitive. Maximum sensitivity is normally achieved by 40 min. Any panretinal disease, which causes rod damage or dysfunction may cause night blindness and can be quantitated by the dark adaptation test. Measuring the final rod threshold in several retinal locations after 40 min of dark adaptation is a good screening procedure for assessing night vision. This test is useful in functionally accessing complaints of night blindness in cases where dysfunction at night has vocational significance. The mechanisms of color vision are partly understood, and are based on pathways that involve specific cone receptors for red, green, and blue, whose signals are integrated by the visual system ([14](#)).

Researchers using molecular genetic techniques have confirmed that human trichromacy is determined by distinct cone photoreceptor cells; it was reported that red-green color blindness is caused by alterations in genes encoding red and green visual pigments, and anomalous or partial color blindness conditions appear to be related to hybrid and/or redundant coding ([15](#)). Also reported were the molecular structures of green, red, and blue pigment genes, and the chromosomal locations of rhodopsin (chromosome 3) and blue pigment (chromosome 7). The red and green pigment genes were previously known to be on the X-chromosome. Many retinal degenerations affect the cones, giving color vision abnormalities. These can be quantitated by color and intensity matching (Nagel anomaloscope), the Farnsworth-Munsell hue discrimination test, and color plates. In a broad sense, color vision defects may be divided into two groups: congenital and acquired. While hereditary congenital color vision defects are almost always red-green, affecting 8% of males and 0.5% of females, acquired defects are more often of the blue-yellow variety and affect males and females equally. There are a number of important clinical distinctions between the congenital and acquired color vision defects.

Patients with congenital color vision defects rarely misname colors, whereas patients with recent changes in color vision of an acquired nature will typically use incorrect color names or report that the color appearance of familiar objects has changed. Except in rare cases, congenital color vision defects affect the two eyes equally. In striking contrast, acquired color vision defects frequently affect one eye more than the other.

Congenital color vision defects are constant in type and severity throughout life except for changes that

occur with aging. Acquired color vision defects generally vary in type and severity, depending on the location and source of associated ocular pathology. Congenital color vision defects generally are not associated with observable retinal or optic nerve pathology, whereas acquired color vision defects frequently have macula changes.

The fluorescein angiogram is a good test for identifying retinal vascular and RPE abnormalities or alterations, since many retinal structures are normally impermeable to the fluorescein dye but will leak or stain if diseased, often in distinctive patterns. The diagnosis of some hereditary retinal diseases such as choroideremia, autosomal recessive preserved pararteriolar retinal pigment epithelial (PPRPE) RP12, early dominant RP with normal ERG, and X-linked carrier states may be supported by changes seen on the fluorescein angiogram, but are not apparent on clinical examination. Many of the hereditary retinal degenerations including a rare autosomal recessive cone degeneration, fundus flavimaculatus (Stargardt's disease), and some cases of RP will demonstrate a "dark choroid" or hypofluorescence of macular areas on fluorescein angiography. The reason for this appears to be a buildup of abnormal deposits within retinal pigment epithelium that blocks the choroidal fluorescence that is normally transmitted through this layer.

#### 138.2.4 Optical Coherence Tomography

Optical Coherence Tomography is a non-invasive cross-sectional imaging method using low-coherence interferometry to provide detailed morphometric information on retinal structure (16). It has become an important method in the diagnosis and follow up of RP, Stargardt disease (17) and albinism (18). This test is used increasingly in the diagnosis and management of inherited retinal diseases.

#### 138.2.5 Inheritance Patterns

The use of pedigree analysis has been an important discriminator in classifying the various hereditary retinal disorders. Many diseases such as RP, fundus flavimaculatus, and cone dystrophy, within each group, have a similar fundus appearance, yet multiple inheritance patterns are found for each retinal disorder type. Within the RP group, classification by inheritance pattern is a preliminary method to help select the correct laboratory approach for mutational analysis. If molecular diagnosis is not successful, then the clinical diagnosis based on phenotyping, electrophysiological results, and inheritance patterns is employed.

#### 138.2.6 Genetic Counseling

If the gene has not been found for a patient's retinal dystrophy, the two most important criteria in counseling patients with hereditary retinal degenerations are

a specific and correct diagnosis and an accurate pedigree that is interpreted correctly. This may take several patient visits to accomplish. Establishing a specific clinical diagnosis may require physiological or psychophysical testing, examining other family members, and the services of an ophthalmologist familiar with these diseases. Some of the retinal degenerations are inherited in established patterns, and if the diagnosis is unequivocally made, and gene testing is not available, then genetic counseling can be performed with reasonable certainty; for example, choroideremia (X-linked recessive), Best's disease (autosomal dominant), and Usher I (autosomal recessive) would be diseases in which counseling could be performed with reasonable certainty even if a family history was not available. However, other retinal degenerations such as the pigmentary retinopathies, fundus flavimaculatus, cone dystrophies, and vitreoretinal degenerations are documented to be inherited in more than one inheritance pattern, and mutation identification is needed, or if not available, a careful pedigree with examination and testing of other family members would be necessary in order to accurately counsel the patient. Clinical features usually are consistent within families, but can vary between pedigrees. Many of these diseases are pleiotropic, and counseling should rely heavily on the pedigree if the disease-causing gene is not known.

Occasionally, because complete pedigree or clinical information cannot be obtained, reliable genetic counseling cannot be given and it is best to carefully relate this to the patient. Unfortunately, misinformation is frequently given to this group of ophthalmological patients, with the most common misconception being that RP is always inherited through the female (X-linked recessive) when in the United States this is the least common mode of inheritance, representing approximately 10% of the RP population.

### 138.3 PIGMENTARY RETINOPATHIES/RETINITIS PIGMENTOSA

Retinitis pigmentosa (RP) is the name commonly given to a group of diseases characterized by progressive visual field loss, night blindness, and abnormal or nonrecordable ERG (Tables 138-1 and 138-2). Most patients will show pigment deposition in the retina along the blood vessels with optic nerve pallor and arteriolar narrowing in early stages advancing to characteristic 'bone spicule' pigmentary pattern in later stages (Figure 138-3a, b). Histological studies of RP retinas suggest that the source of the pigment is the retinal pigment epithelium (RPE). The retinal deterioration taking place is intrinsic to the disease process and does not appear to be related directly to the pigment deposition process, which is a secondary effect. Whether the pigment contributes to the deterioration of retinal function is doubtful. Localized retinal pigment deposition is commonly seen in processes injuring

**FIGURE 138-3** (a) Early stages of RP showing arteriolar narrowing and pigmentary deposits along the blood vessels. (b) Typical “bone-spicule”-like pigmentary deposits seen in RP. While RP comprises many different diseases, there is a common final pathway of degeneration leading to the retinal pigment deposition. (c) Optical coherence tomography showing cystoid macular edema in a patient with RP. (Courtesy: Dr Jiong Yan, Emory University.)

or destroying the RPE layer, and the RP pigmentary pattern can be regarded as a common degenerative pathway for a number of different acquired and hereditary retinal degenerations (Tables 138-1 and 138-2). Clinical classifications of RP are becoming less important as gene mutational analysis is now giving much clearer answers on the etiology of these disorders. Some clinicians reserve the term RP for the electroretinographically determined group with “rod-cone” degeneration in which patients have early night blindness and the ERG is abnormal, with the rod ERG being more abnormal or nonrecordable compared to the light-adapted cone ERG, which may show some response. However, recent reevaluation of classification by a number of RP centers shows that there are at least two RP groups based on whether the patient has diffuse rod loss or a mixed loss of cone and rod function. The latter group usually has electroretinographic changes in which the cone function is worse than rods, and the diagnostic term cone-rod degeneration has been used. These individuals generally have later night blindness and some have no nyctalopia until they have visual

fields less than 10°, and many of these patients have no retinal pigment deposits and could be termed “retinitis pigmentosa sine pigmento.” Cone-rod RP patients also have progressive visual field loss, retinal degeneration, vascular attenuation, optic atrophy, and RPE damage. The inheritance pattern can be autosomal dominant, autosomal recessive, X-linked or mitochondrial.

The pigmented retinopathies can be divided into two large groups, primary RP in which the disease process is confined to the eyes, with no other systemic manifestation; and secondary pigmentary retinopathy, a rarer occurrence in which the retinal degeneration is associated with single or multiple organ system disease. The list of RP syndromes, or diseases in which a panretinal degeneration is associated, is long (Retnet, OMIM), and the presence or absence of the retinal degeneration depends on the pathophysiological mechanisms and duration of the disease in question (19). The etiological relationship of the retinal degeneration to most of these syndromes is unknown. In some cases such as the mucopolysaccharidoses, mannosidosis, Batten’s disease, and Refsum’s disease, abnormal metabolic products are toxic to the retina and cause degeneration. Please find additional details in references discussing the individual diseases.

### 138.3.1 The Primary Pigmentary Retinopathies

Because over 90 forms of RP have been identified, either by gene or linkage identification, the classification is shifting to classification by gene diagnosis. However, it is still necessary to be aware of clinical classifications of the primary pigmentary retinopathies by inheritance type and subdivision, often using the pattern on the ERG or psychophysical measurement of rod function (Table 138-1). In general, morphological retinal appearance is not used to classify the entities in Table 138-1 because of nonspecificity of the patterns seen in the pigmented retinopathies and because of problems of secondary gene expression, which may alter the fundus appearance in patients with the same genetic type of pigmented retinopathy.

All forms of inherited RP are progressive, though “delimited forms” have been noted that appear clinically to be milder. One of these types is “sector RP” in which the apparent retinal degeneration is mainly localized to the inferior and inferior nasal areas of the retina. Many cases of sector RP have been found to be from rhodopsin gene mutations. In rhodopsin mutation rodent models light was found to cause retinal toxicity, and documentation of light toxicity in humans has been reported in rhodopsin Pro23His mutations, which are associated with sectoral RP. Studies in transgenic rodents with rhodopsin mutations have confirmed that this group is more sensitive to the toxic effects of light exposure.

Analysis of disease progression by inheritance type has been made, suggesting that as a group RP has a 4–5% loss per year of existing field, but all such analyses have

the handicap that multiple types of RP may be included within each inheritance type, each with its own genetic expression and each influenced by secondary factors. Another problem is that studies may focus on probands who may have the most severe expression of the disease.

The frequency of RP varies with country and race being studied. The highest known incidence is in the Navajo Indian, with 1 in 1800 being affected. The overall US frequency has been calculated to be 1 in 3700 with nearly 15–20% being autosomal recessive, 20–25% autosomal dominant, and 10–15% X-linked recessive (20). Up to 50% of cases presenting in the United States have no family history. It is generally assumed that most of these cases represent autosomal recessive RP, though undoubtedly a few are autosomal dominant with reduced penetrance or are X-linked recessive in which the last affected male was several generations past (Figure 138-4).

Rare cases of mitochondrial and X-linked dominant inheritance have been reported. The role of environmental (nongenetic) causes of RP is difficult to determine, but rare environmental causes may be found in a minority of isolated cases. Prenatal rubella or CMV infections may cause pigmentary retinopathies. Upon careful searching, many isolated cases find other relatives who had RP, night blindness, or blindness of unknown etiology. This discovery process may take several visits but allows for more accurate genetic counseling and potential gene diagnosis.

### 138.3.2 Management of Retinal Dystrophies

Most retinal dystrophies are relatively rare. Most ophthalmologists have limited experience in working with retinal dystrophy patients and may have limited experience in the principles of medical genetics. Most retinal dystrophy patients are anxious because of their uncertainty regarding possible blindness; it is therefore important to ensure that they are evaluated by specialists who are familiar

with these disorders. It is important to order the correct tests and to obtain a full pedigree. Once the information is assembled, the correct diagnosis must be related to the patient along with the significance of the findings, prognosis, and possible treatments. Most patients want to know about the latest research on their disease. Unfortunately, accurate information is not always supplied to them. The retinal dystrophy field is complicated, and it is desirable to refer these patients to specialists who are familiar with medical genetics and sophisticated electrophysiological testing. For example it is not unusual for RP patients to be told that they will go blind within one year, when in fact the disease is a chronic degenerative problem, and the majority of patients do very well for decades. Some RP patients are told not to have children, when in fact careful scrutiny of most pedigrees show that offspring are not at immediate risk unless the patient has an autosomal dominant disease or X-linked disorder.

Management of RP includes regular ophthalmological checkups and careful evaluation of the retinal degeneration to ensure that the type is diagnosed as specifically as possible. Not only is this important from a research point of view, but it also may help to identify the inheritance type in cases in which there is an inadequate family history. Frequently the most meaningful electrophysiological information is obtained early in the disease process. In addition, basic documentation by visual field and electrophysiological/psychophysical testing helps answer questions that invariably arise as to how severe the condition is and how fast it is changing. Many of these patients will benefit from counseling to deal with narrowed visual fields and night vision, and use of low vision aids. Advanced cases may need vocational rehabilitation and mobility training. While many patients will maintain reasonable central vision for years, some are legally blind (visual field  $<10^\circ$ ) and in the United States are entitled to more favorable tax treatment and governmental benefits due to this disability. Driving is often an issue with this group of patients. Many jurisdictions are aggressive about denying RP patients the right to drive. Interestingly, there have been studies that suggest that RP drivers are safer because they know their limitations. In many RP types, good central vision is maintained until advanced stages of the disease, and the issue is the size of the visual field. Patients must stop driving when their visual field is narrowed to the point where they will miss objects that will be in the path of their car. Common sense management works if the patient is realistic.

RP and some other retinal dystrophy patients commonly have additional problems such as headaches, light flashes, and light sensitivity, which should be treated symptomatically with standard headache medications and UV sun screening glasses. Careful studies of retinal degeneration have demonstrated that the retina remodels where surviving neurons develop new dendrites to adjacent cells (21). This may be the source of many aberrant flashes perceived by patients. Maintaining optimal

**FIGURE 138-4** Congenital RP and macular colobomata (staphylomata) is an autosomal recessive disorder. The macular area does not form, leaving a central “scooped-out” appearance; a diffuse pigmentary retinopathy is present from an early age.

vision with glasses and optical aids, and checking for treatable diseases such as cataract and glaucoma should be performed annually. If careful selection criteria are used, RP patients with cataracts may benefit from cataract surgery without fear of worsening the RP. In some patients, however, the visual symptoms from cataract become severe at about the same time that the visual field becomes noticeably narrowed; cataract surgery does not restore lost visual field (unless the cataract is severe), which is disappointing to some RP patients despite preoperative counseling that only the visual acuity is likely to be improved by surgery. Posterior chamber intraocular lenses give the broadest possible visual field and are strongly recommended for RP patients.

### 138.3.3 Treatment

A number of options for pigmentary retinopathies are currently under clinical trial. The use of ultraviolet absorbing lenses with or without tint should be encouraged. Vitamin supplements in adult patients (over the age of 18) with RP and in good general health are recommended; 15,000IU/day (palmitate form) of a vitamin A supplement under medical supervision is advised. It is suggested that they avoid high doses of vitamin E. The patient should be advised to avoid toxic levels of any vitamin or mineral (22). About 10% of RP patients will have retinal edema or cystoid macular edema during the course of their disease. There are several etiologies underlying this complication, including inflammatory reactions after cataract surgery, autoimmune components, and rarely vitreous-macular traction. Various therapies have been used with moderate success, including nonsteroidal anti-inflammatory drugs for postoperative cataract edema, and standard immunosuppressive agents for more extensive retinal edema (23). Anti-carbonic anhydrase inhibitors have shown some limited success in some patients also. Maintaining optimal vision with glasses and optical aids and checking for treatable diseases such as cataract and glaucoma should be performed annually. If careful selection criteria are used, RP patients with cataracts will benefit from cataract surgery without fear of making the disease worse. In some patients, however, the visual symptoms from cataract becomes severe about the same time that the visual field becomes noticeably narrowed; cataract extraction does not restore lost visual field (unless the cataract is severe), which is disappointing to some RP patients despite preoperative counseling that only the visual acuity is likely to be improved by the surgery. Posterior chamber intraocular lenses give the broadest possible visual field, and current knowledge would suggest that RP patients undergoing cataract surgery would be advised to have only this type of lens implant.

Several clinical trials, including therapy with valproic acid, DHA supplementation, retinal prosthesis, intelligent medical implant and genethrapy are underway and can be looked up at [www.clinicaltrials.gov](http://www.clinicaltrials.gov).

## 138.4 LEBER'S CONGENITAL AMAUROSIS

Leber's congenital amaurosis is characterized by an infant with poor vision since birth and has a nonrecordable ERG. The fundus examination may initially be normal, but over time pigmentary deposits usually develop (Figure 138-5). A searching nystagmus develops in early infancy and is common by two years of age.

A second form of Leber's is characterized by infantile night blindness, but the infant clearly can see. Symptoms of visual field loss are frequently noted by age 4. By this time an early pigmentary retinopathy may be noted, and the ERG is severely affected, but the child may maintain tubular fields with a visual acuity through middle adulthood in the 20/70–20/200 range. This form has been called Juvenile Leber's amaurosis, and a number of juvenile and LCA genes with less severe expression have been identified (Table 138-1).

Another form of congenital RP consists of pigmentary retinal degeneration and macular coloboma or staphyloma; occasionally keratoconus and mild skeletal abnormalities are found. All the previously mentioned forms of early RP are inherited in the autosomal recessive fashion, and all patients usually have varying degrees of hypermetropia. Some patients with ARRP have this phenotype, but the others remain unknown.

Finally, there is a rare form of autosomal dominant infantile onset RP that manifests early, but behaves in many ways like a very early onset, progressive cone-rod degeneration. These patients have normal appearing retinas until their adult years, but the visual fields progressively constrict and the patients become night-blind. These patients have been found to have overlapping

**FIGURE 138-5** Leber congenital amaurosis with an almost normal fundus appearance other than mild pigmentary changes.

segment of exons 3a and 3b in CRX gene resulting in a 12-bp deletion in codon 146.

### 138.4.1 Treatment

Gene replacement therapy is in clinical trial for Leber Congenital amaurosis caused by *RPE65* gene and has shown promising results (24).

## 138.5 THE PRIMARY CONE DEGENERATIONS

There are a number of different cone dysfunction syndromes that manifest from birth, or cone degenerations that occur in teenage or even later adult life. The group is diagnosed by an abnormal or nonrecordable photopic ERG and a normal scotopic ERG, while peripheral visual fields remain normal. All three inheritance patterns have been found in the cone degenerations. The genes causing this disorder are outlined in Table 138-1.

Cone degenerations occurring after infancy generally fall into two age ranges, with symptoms beginning ages 4–8 and then from the late teen years to age 30. The visual acuity may range from 20/50 to 20/400. Because the majority are autosomal recessive, there is seldom a family history; autosomal dominant pedigrees of cone degeneration have been documented and do not tend to become symptomatic until adolescence to the mid-1920s. There are likely multiple genetic forms of both the autosomal recessive and dominant cone degenerations. An adult-onset X-linked recessive cone dystrophy with a tapetal-like sheen (beaten metal appearance) and Mizuo–Nakamura phenomenon in which the fundus appearance changes with dark adaptation has been reported in several pedigrees, but the gene has not yet been determined.

Symptoms of cone dysfunction include loss of visual acuity, photophobia (light intolerance), and progressive color vision loss. Retinal pigment epithelial loss and pigment deposition may be seen in later stages. Mild to severe temporal optic atrophy is commonly seen. Demarcated circular macular lesions with or without tapetal reflexes or macular atrophy may be seen.

The cone degenerations should not be confused with congenital color blindness, in which there are color deficits for specific colors but no associated retinal degeneration. Patients with congenital color blindness (protanopia, deutanopia, and tritanopia) have normal visual acuity and do not show signs of progressive disease. The molecular mechanisms of color blindness have been well delineated by Nathans.

### 138.5.1 Achromatopsia

Achromatopsia (rod monochromatism) is a rare autosomal recessive form of cone dysfunction that is characterized by a near normal fundus appearance, nystagmus, a nonrecordable photopic ERG, and normal to near

normal scotopic ERG that remains stable. Vision is usually 20/200–20/400. Many patients demonstrate intense photophobia, increased reflexes from the retina surface, and may show temporal optic atrophy. Slight macular retinal pigment epithelial disturbances may be seen, but the appearance is essentially normal. The achromatopsia causing genes include *CNGA3*, that codes for the cone photoreceptor cGMP-gated cation channel, alpha subunit, cyclic nucleotide-gated channel, beta-3, *CNGB3* causing achromatopsia in the Pingelapese and *GNAT2* (25).

Dominant cone dystrophy linked to 6p21.1 was found to be due to mutations in guanylate cyclase activator 1A (*GUCA1A*), a calcium binding protein that is expressed in photoreceptor outer segments.

### 138.5.2 Blue Cone Monochromatism

X-linked blue cone monochromatism has similar features to rod monochromatism but is usually milder in expression. These patients are often diagnosed as having “congenital nystagmus,” and initially the correct diagnosis is missed until an ERG is performed. Two forms of blue cone monochromatism has been found by Nathans due to mutations in the green and red cone opsins, *OPN1LW*, and *OPN1MW*.

### 138.5.3 Fleck Retina Diseases (Fundus Flavimaculatus, Fundus Albipunctatus, Retinitis Punctata Albescens, Familial Drusen)

The clinical diagnosis of a specific fleck retina disease is made by a combination of ophthalmoscopy, electrophysiological and psychophysiological testing, clinical evidence of stationary or progressive disease, evaluating the visual field test. Photographs and the fluorescein angiogram may be particularly valuable in diagnosing Stargardt’s disease. These groups of disorders are characterized by discrete yellowish or yellow-white lesions at the level of the retinal pigment epithelium (RPE) that may be scattered throughout the fundus or confined to the posterior pole. These diseases are sometimes mistakenly called “fleck retina syndrome,” which is not correct as each disease is quite distinctive in appearance and/or clinical course. The genes for most of the fleck retinal diseases have been found.

### 138.5.4 Fundus Flavimaculatus (Stargardt’s Disease)

Fundus flavimaculatus or Stargardt’s disease is characterized by linear, or fish scale-shaped (pisciform) yellow lesions (Figure 138-6), which are most often seen in the macular region, but may extend out to the equator regions in distribution. Histological examination of donor eyes demonstrates lipofuscin deposits retinal pigment epithelial cells (RPE), which cause hypertrophy and

**FIGURE 138-6** Fundus flavimaculatus, one of the fleck retina diseases, is characterized by linear or fish scale flecks scattered throughout the posterior pole. Some patients develop atrophic macular and/or paramacular lesions. All cases are due to mutations in the ABCA4 gene.

clumping of localized RPE, which appear as “flecks” when compared to the adjacent normal-appearing RPE cells.

Fishman and Krill categorized fundus flavimaculatus into four stages of severity. Fundus flavimaculatus typically starts with a ring of yellow flecks surrounding the fovea with normal ERG and EOGs, and vision varying from 20/30 to 20/100. On fluorescein angiography the macula region is hypofluorescent (“dark choroid”) and the flecks may show focal hyperfluorescence (window defects) on fluorescein angiogram. There is a wide variety of expression, with varying age of onset and with some patients experiencing severe macular degeneration, and others remaining stationary. Some patients stabilize for a time with foveal islands of intact RPE with severe parafoveal RPE loss. Fundus flavimaculatus has been found in both autosomal dominant and recessive pedigrees (the latter most common). If the patient does not have macular involvement, the disease may be a relatively benign problem.

The ERG and EOG are normal to subnormal correlating with the amount of fundus involvement. Some patients may experience mild night blindness. The Goldmann visual field using smaller isopters may demonstrate a central scotoma, and a few patients may show some contraction of the peripheral field.

The Stargardt ABCA4 gene maps to chromosome 1p21–p13 and is part of the ATP-binding cassette (ABC) family, which is involved in energy-depending transport across membranes. The ABCA4 gene contains at least 50 exons and spans about 150 kb. The gene has high polymorphism. The gene has been implicated in fundus flavimaculatus, Stargardt’s disease, cone-rod dystrophy, and RP. The ABCA4 gene appears to have interaction with other genes to be disease-causing since many patients have been found to only have one allele with an ABCA4 mutation.

**FIGURE 138-7** Familial drusen are inherited in the autosomal dominant manner, characterized by accumulation or deposits of yellow material at the level of the retinal pigment epithelium. This fundus image shows radial distribution of drusen seen in Doyme honeycomb retinal dystrophy or Malattia Leventinese syndrome caused by mutation in the EFEMP1 gene.

### 138.5.5 Familial Drusen (Doyme Honeycomb Dystrophy, Malattia Leventinese)

The term “drusen” is used in ophthalmological nomenclature to refer to yellow–white deposits that are seen in the retina at the level of the retinal pigment epithelium with the ophthalmoscope (Figure 138-7). Retinal drusen should not be confused with golden yellow “drusen” of the optic nerve head, which are calcifications in the nerve substance inherited in the autosomal dominant fashion or an isolated occurrence. Unfortunately the retinal and optic nerve head types of drusen have been called with the same name.

Krill divided retinal drusen into hereditary and secondary degenerative forms. Familial forms are inherited in the autosomal dominant mode and occasionally may have incomplete penetrance. They typically start to appear at age 20–30, but may not become clinically significant for 10–20 more years. The late onset of symptoms increases the difficulty of establishing the autosomal dominant pattern, since many older relatives who were affected are deceased.

Initially the drusen begin as small round dots in the posterior pole, and over many years they increase in number and become more confluent. Pigment clumps may appear, and atrophy of the RPE may occur, leaving an atrophic macular scar in later years. A few cases have enough pigment clumps to entertain the diagnosis of RP. The extent of the drusen is variable, with most cases limited to the posterior pole. Retinal edema, subretinal hemorrhage, and neovascularization may occur in familial drusenosis, similar to the pathophysiological processes occurring in other types of macular degeneration. There is no known

effective treatment for this primary retinal degenerative process; secondary problems such as subretinal neovascularization occasionally may be treated with photocoagulation. The ERG is usually normal, though occasionally is mildly abnormal. The EOG is commonly abnormal.

The gene for Doyme honeycomb retinal dystrophy and Malattia Leventinese has been designated EFEMP1 for fibulin-like extracellular matrix protein 1, which maps to 2p21-p16.

### 138.5.6 Retinitis Punctata Albescens and Fundus Albipunctatus

Retinitis punctata albescens (RPA) and fundus albipunctatus (FA) are often compared because their phenotype can be identical. Both RPA and FA patients have numerous discrete white to yellow dots scattered throughout the fundus (Figure 138-8). RPA is progressive while FA is stationary. RPA is caused by mutations in RLBP1, a gene encoding cellular retinaldehyde-binding protein. FA is caused by mutations in RDH5, the gene encoding 11-cis retinol dehydrogenase.

Both conditions are inherited in the autosomal recessive fashion, although rare pedigrees of autosomal dominant FA have been reported. FA was classified as a form of congenital stationary night blindness by Krill. Clinically RPA acts like typical RP, with night blindness, progressive visual field loss, and retinal vessel attenuation. With time the focal yellow deposits may become pigmented.

In FA, patients are night-blind, but the visual acuity and visual fields remain normal. The ERG and EOG have been reported to be normal to abnormal. The retinal deposits can be stationary, increase, or regress. Marmor and others have reported patients with FA in which the ERG and EOG were abnormal initially and become

**FIGURE 138-8** Retinitis punctata albescens, characterized by discrete white-yellow deposits at the level of the retinal pigment epithelium seen throughout the retina. FA, a form of congenital stationary night blindness, has a similar appearance.

normal after 3 or 4 h of dark adaptation. These findings are consistent with abnormal photoreceptor pigment regeneration and help to distinguish FA from other types of congenital stationary night blindness.

Other conditions that can give scattered retinal spots include the fleck retina of Kandori, macular degeneration with cholesterol deposits, *peau d'orange* spots of pseudoxanthoma elasticum, vitelliruptive macular degeneration with multiple lesions, Bietti's crystalline retinopathy, the lacunae of Aicardi syndrome, the carrier state for X-linked albinism, punched-out lesions of presumed histoplasmosis syndrome, severe vitamin A deficiency, and scattered lesions of "birdshot retinochoroiditis." Many RP patients have fine scattered drusen as well as loss of the retinal pigment epithelium in discrete lobular patterns, which may give patterns somewhat similar to the fleck retina group.

### 138.5.7 Vitelliform Macular Dystrophy (Best Disease)

Best's disease is an autosomal dominantly inherited macular dystrophy that is known for its "egg yolk" macular lesion (Figure 138-9) that occurs early in the degenerative process, usually between 3 and 20 years of age. Krill reports having seen the lesion in a 16-month-old, and states that earlier lesions have been reported. Some family

**FIGURE 138-9** (a) Best disease, or vitelliruptive macular degeneration, has a distinctive "egg yolk" macular lesion in its early cystic phase. It is a dominant disease caused by mutations in bestrophin gene. (b) Optical coherence tomography showing subretinal lipofuscin deposits. (Courtesy: Dr Amy Hutchinson, Emory University.)

members do not develop the macular lesion, but always will have an abnormal EOG, which can be used to identify those patients at risk without findings who wish counseling. A natural history of this disorder has been published. Those affected have normal ERGs and abnormal electroculograms. The bestrophin gene is located on chromosome 11q13 and has been localized to the basement of the retinal pigment epithelium. The “egg yolk” lesions appear cystic, filled with a golden-yellow material. Vision is not as disrupted as might be thought from the appearance of the lesion, ranging from 20/30 to 20/60 in the early stages. Some patients will have multiple posterior pole lesions. However, if subretinal hemorrhage occurs, the vision may be poor. The natural course is for the cystic lesion to dissipate and leave an atrophic macular scar with mildly decreased central vision. Several histopathological reports have found increased cytoplasmic inclusions and lipofuscin granules in the retinal pigment epithelium; an abnormal fibrillar material was found in several retinal layers.

### 138.5.8 Albinism

Albinism is characterized by reduced pigmentation in the skin and hair with ocular involvement. Patients with any form of albinism may have ocular or visual disorders, ranging from severe to mild problems. In the past, albinism has been divided into oculocutaneous albinism and ocular albinism. In both there is a partial or total reduction of melanin deposition on melanosomes, due to mutations in genes involved in the biosynthesis of melanin pigment. There are multiple forms of oculocutaneous albinism.

Regardless of the type of albinism, the ocular involvement generally conforms to one of two clinical patterns: (i) congenitally subnormal visual acuity and nystagmus, and (ii) normal or only minimally reduced visual acuity and no nystagmus. The first pattern is true albinism, while the latter circumstance has been termed albinoidism because of the milder visual consequences. Both patterns share common clinical features of photophobia, iris transillumination, and hypopigmented eyes. They differ by whether the fovea develops; hypoplasia of the fovea is a sign of true albinism. Mutations in four genes OCA1, OCA2, OCA3 and OCA4 cause OCA, OA1 gene causes X-linked ocular albinism, and there are several genes causing Hermansky-Pudlak syndrome and Chediak-Higashi syndrome (26).

A common finding to all types of albinism is abnormal retinogeniculostriate projections, with many of the temporal hemiretinal nerve fibers decussating rather than projecting ipsilaterally to the geniculate body. These misprojections can be measured and diagnosed by visual evoked cortical potential testing. The first form of ocular albinism was described by Nettleship in a large X-linked recessive pedigree. The affected males had subnormal visual acuity, translucent irides, congenital nystagmus, photophobia, hypopigmentation of the fundus, and hypoplasia of the fovea. Pigmentary mosaicism is common in female carriers, who may be symptomatic. An

X-linked ocular form was reported in black patients who had moderately pigmented fundi and no transillumination of the iris, but patients with X-linked recessive ocular albinism had giant pigment granules on microscopic examination of skin biopsy.

Autosomal recessive ocular albinism is relatively common, and females are as severely affected as are males. Patients have decreased visual acuities in the 20/100–20/400 range, translucent irises, congenital nystagmus, photophobia and strabismus. Patients are lightly pigmented at birth, and usually develop further pigmentation with age. In general, the more pigmentation that the patient demonstrates, such as around skin hair follicles and particularly in the retinal pigment epithelium in the posterior pole, the better is the visual prognosis. Many patients demonstrate improvement in their nystagmus and visual acuities as pigmentation develops with age. Genetic counseling depends on carefully establishing the inheritance pattern and gene testing of the OCA genes and OA1 gene that are clinically available.

### 138.5.9 X-Linked Retinoschisis

The term “retinoschisis” refers to a splitting of the neurosensory retina, which at times may mimic a retinal detachment when viewed with the ophthalmoscope. There are three forms of retinoschisis: senile onset with no known inheritance pattern, which involves a splitting of the nerve fiber layer of the retina; a secondary form that is mainly associated with tractional retinal detachments; and congenital X-linked recessive retinoschisis.

Congenital X-linked retinoschisis differs in significant ways from the senile form. The schisis occurs in the inner retina and may be slowly progressive. Eventually in some cases it may result in a panretinal degeneration. The phenotype is variable, even within families. The process also involves the macula, and one of the first signs that are seen is a microcystic elevation and radiating retinal folds of the macular area (Figure 138-9), but central vision may remain relatively good, typically in the 20/60 range. Several cases of macular schisis without peripheral involvement have been seen, but occur very infrequently. Peripheral schisis may or may not be present on a single examination, but usually it will be found with repeated examinations. Male children with the disease will frequently present with vitreous hemorrhages from broken retinal vessels in areas of schisis. Pigmentary deposits may develop in these areas destroyed in the disease process, so that advanced cases of X-linked retinoschisis can be mistaken for RP (Figure 138-10). The clinical diagnosis may have to be confirmed by viewing younger affected male family members.

The retinal inner layer damage is reflected in the ERG; early in the disease the a-wave is normal or near normal, and the b-wave is attenuated in proportion to the amount of retinal schisis, typically giving a “negative

**FIGURE 138-10** (a) Congenital juvenile X-linked retinoschisis, with typical microcystic lesions of the maculae early in the disease. The retinoschisis may look similar to retinal detachment and usually develops later in childhood. The retinoschisis may be found during evaluation for vitreous hemorrhage, as the retinal vessels may break and bleed during the schisis process. (b) Optical coherence tomography showing cystic lesions in the neurosensory retina. (Courtesy: Dr Baker Hubbard, Emory University)

waveform” (see Table 138-2). Negative waveforms of the bright flash dark-adapted ERG occur in diseases in which the middle retina is affected and the photoreceptors are generally unaffected, resulting in an a-wave and no effective b-wave. The ERG may become extinguished in cases in which there is extensive retinal damage. The EOG and dark adaptation test are normal to abnormal depending on the stage of the disease.

The gene for the X-linked form of retinoschisis, retinoschisin, has been identified, and was initially found to be localized to the photoreceptor; however, subsequent studies have shown that the protein is transported to Müller cells. Presumably, retinoschisin is essential for Müller cell health, since mutations in its coding results in their degeneration. However, Wu reports that the mutational damage localizes to the bipolar synapse. Müller cells span the layers of the retina, with their endplates forming the inner limiting membrane and the distal ends forming the outer limiting membrane at the inner segments. Loss of the bridging extracellular retinoschisin matrix appears to be a key to the changes seen in retinoschisis.

**FIGURE 138-11** Advanced juvenile retinoschisis in a 63-year-old man, demonstrating a pigmentary retinal degeneration with the appearance of RP.

### 138.5.10 Choroideremia

Choroideremia is an X-linked recessive retinal degeneration that clinically behaves like typical RP. Affected males develop symptoms of peripheral vision loss and night blindness from age 5–20 years. Occasionally a female carrier will develop symptoms and will have a mild retinal degeneration on ophthalmoscopic examination, though females are rarely seen with the disease. Affected female cases have been hypothesized to be extreme examples of lyonization. The majority of choroideremia carriers show some fundus signs, including subretinal pigment clumping and an appearance of granularity to the retinal pigment (Figure 138-11). When carriers are tested, usually the ERG, dark adaptation study and visual field examination are normal, but carriers with extensive fundus changes will demonstrate abnormalities on testing and may show progression with time. Usually the rate of progression does not functionally affect the carrier. Affected males have a lobular loss of the retinal pigment epithelium (RPE) and the underlying choriocapillaris, which starts in the equator region of the fundus with the retinal degeneration progressing toward the anterior retina and posterior pole (macula and surrounding retinal area) (Figure 138-12). Because the process is insidious, patients are frequently seen for the first time in a moderately advanced state in which the posterior pole has the only remaining normal tissue, allowing the patient good central but little side vision. The central retinal area appears to be more resistant to the disease process, which is also true for many other types of RP and central vision is often good even in advanced stages. After many years some patients will lose this central vision. The disease process may take 40 or 50 years to reach this tragic end point. Even with this extreme visual loss, many patients maintain some perception of light, or even hand motion vision. When recordable, the ERG

**FIGURE 138-12** Fundus images of Choroderemia carrier, an X-linked recessive retinal degeneration due to a mutation of geranyl transferase showing subretinal pigment clumping and an appearance of granularity to the retinal pigment.

shows a rod-cone degeneration. The EOG is abnormal, and dark adaptation testing shows final rod thresholds 2.4–4.0 log units elevated, proportional to the amount of retinal degeneration. The gene for choroideremia was described by Cremers, and has been described as a Rab escort protein defect (REP-1) resulting from mutations in the RAB27A gene. REP-1 acts in the prenylation of GTPases, regulators of intracellular protein trafficking. Clinically, the diagnosis is confirmed by the distinctive fundus pattern on the fluorescein angiogram in which there is frequently a scalloped pattern of RPE loss with no increased pigmentation to the RPE (Figures 138-13 and 138-14). Takki clearly demonstrated the biochemical difference between gyrate atrophy and choroideremia patients even though the fundus pattern is similar. The difference in inheritance patterns (AR vs. XL) in the two disorders also helps to differentiate them.

The initial diagnosis may be difficult because there are several different fundus appearances to choroideremia, and the RPE and choriocapillaris loss may not be obvious in all cases on ophthalmoscopy. If a patient clearly has X-linked recessive inheritance and choroideremia cannot be ruled out, then a fluorescein angiogram will clearly differentiate whether there is choriocapillaris loss and large choroidal vessel preservation.

Several syndromes with fundus features of choroideremia have been documented; van den Bosch reported an X-linked recessive kindred with mental retardation, acrokeratoses verruciformis, anhidrosis, and skeletal deformity. Ayazi reported a three-generation X-linked recessive family with choroideremia, congenital deafness, and obesity.

Differential diagnosis would include patients with Bietti's crystalline dystrophy, which is an autosomal

**FIGURE 138-13** Fundus images of Choroderemia affected individual with a mutation in the CHM gene with loss of retinal and choroidal layers outside of the macular region, scalloped appearance in mid periphery.

**FIGURE 138-14** Fluorescein angiogram of advanced choroideremia case, in which there is loss of retinal tissue outside the posterior pole with preservation of larger choroidal vessels. Fluorescein angiogram highlights the pattern of intact retinal pigment epithelium and choriocapillaris remaining in the macular area. This X-linked disease is due to mutations in the geranyl transferase Rab escort protein.

recessive disorder and will show posterior pole and occasionally equatorial choriocapillaris atrophy very similar to choroideremia; in these patients there are usually crystalline deposits in adjacent more normal retina and sometimes in the cornea. Patients who have thioridazine [Mellaril] retinal toxicity will have choriocapillaris dropout similar to choroideremia, but the psychiatric background is frequently found on taking the medical history.

Initially patients with gyrate atrophy and a few patients with other types of RP may be confused with choroideremia, since a scalloped pattern of retinal degeneration may be seen. However, distinguishing features are usually noted; gyrate atrophy and RP patients with this pattern do not have X-linked inheritance, and in gyrate atrophy the retinal pigment epithelium has a darker appearance

compared to the blonder fundus in choroideremia. The diagnosis of gyrate atrophy and Bietti's can be confirmed by mutational testing, and plasma ornithine levels or ornithine aminotransferase activity also will confirm if gyrate atrophy is present. RP patients with RPE and choriocapillaris dropout often have bone spicule formation in equator regions, and may demonstrate choroidal sclerosis, and relative preservation of anterior retinal RPE compared to the loss of these structures that is seen in choroideremia.

### 138.5.11 Gyrate Atrophy

A deficiency in ornithine amino transferase leads to ornithine plasma elevations, which are 6–10 times greater than normal and well documented to be associated with gyrate atrophy. Gyrate atrophy is an autosomal recessive disease that may manifest by eight years of age, and sometimes later. Patients develop a scalloped loss of retinal pigment epithelium (RPE) and choriocapillaris, and intact RPE has more pigmentation than normal (Figure 138-15). Myopia and cataracts are also commonly found. The ERG is abnormal to nonrecordable. There is progressive visual field loss and night blindness. It was originally thought that the effects of the hyperornithinemia were restricted to retinal degeneration, but mild systemic effects have been documented, including abnormal EEGs and changes in hair and muscle fibers; no obvious alteration in life span has been noted. Correction of ornithine accumulation prevents retinal degeneration in a mouse model of gyrate atrophy (27).

### 138.5.12 Usher Syndrome

Usher syndrome is the name most commonly given to the association of RP and congenital deafness, whether partial or profound. Some RP patients have acquired deafness in later adult years, and this is not termed Usher syndrome.

**FIGURE 138-15** Gyrate atrophy results from a mutation of ornithine amino transferase, leading to high serum ornithine. Patients with the disease typically have a scalloped loss of retinal pigment epithelium with progressive loss, myopia, and cataracts.

The one exception that confuses the rule is patients with Usher 3A, who have a progressive hearing loss with their RP, which is not typically noted until adult years. Usher 3A is due to clarin-1 a novel 4-transmembrane protein with a possible role in hair cell and photoreceptor synapses. Clarin-1 accounts for 40% of Usher syndrome in Finland; possible digenic deafness with *MYO7A*.

Both the partial and profound forms are inherited in the autosomal recessive manner. Currently there are 12 types of Usher syndrome in which the chromosomal location is known, of which ten have gene isolation (see RetNet).

*USH2A* is caused by mutations in Usherlin at chromosome 1q41, and encodes a protein that possesses laminin epidermal growth factor as well as fibronectin type III domains. A small number of patients with mutations have RP alone without deafness (28). *USH3A* is caused by mutations in *MYO7A*, a common component of cilia and microvilli. *USH1D* is caused by mutations in cadherin-like gene23 (*CDH23*), an intercellular adhesion protein. *USH1C* is caused by the Harmonin gene, a PDZ domain protein. In addition to this moderately well-described syndrome, a number of other genetic conditions and environmental insults may lead to pigmentary retinopathy and hearing loss. By careful study of individual patients and families, the diagnosis of Usher syndrome may be made with relative certainty.

The exact incidence of Usher syndrome has been difficult to determine, but surveys of RP patients suggest that about 10% are profoundly deaf, and ophthalmological examinations of children in deaf schools reveal that approximately 6% have RP. Vernon suggests that the prevalence of Usher syndrome is 3 cases per 100,000, and the carrier state is estimated to occur in about 1 per 100 individuals.

Four clinical subtypes of Usher syndrome have been defined by Merin. These consist of type I of RP with total deafness and no vestibular function; type II with RP, partial deafness, and intact vestibular function; type III with RP, complete deafness, vestibular ataxia, and sometimes psychosis (Hallgren syndrome); and type IV with RP, total deafness, and mental retardation. Studies with computed tomography have demonstrated that Usher syndrome patients have cerebellar atrophy. Patients with phytanic acid storage disease appear to meet the criteria for Merin type IV Usher's syndrome although it is not clear whether Merin described the same entity. Hallgren syndrome may be an environmentally induced problem occurring in Type I Usher patients since it has not been reported outside of Sweden, and the psychoses that some patients develop have been hypothesized to be related to the long hours of winter darkness.

Those affected with Usher syndrome are either congenitally deaf (deaf mutes) or they may be afflicted with partial deafness, which can be detected clinically by the speech impairment this causes. There is some variability in the progression in those patients who are partially deaf, and while not common, abrupt deterioration has been reported at puberty. The hearing defect is described as a

sensorineural loss, affecting mainly the higher range of frequencies bilaterally. The RP is slowly progressive over many years, and many of these individuals eventually will become blind.

### 138.5.13 Other Inherited Retinal and Choroidal Diseases

There are numerous hereditary primary and secondary retinal diseases, which cannot be covered in this overview, but the more common or well known ones are presented in Table 138-2. Sources for studying these diseases further would include McKusick's Mendelian Inheritance in Man (OMIM) at [www.omim.org](http://www.omim.org) and RetNet, the Retinal information Network, at <http://www.sph.uth.tmc.edu/RetNet>.

### Biography

**Dr Suma Shankar** joined Emory University in January, 2010 with joint appointment in the Department of Human Genetics and the Department of Ophthalmology. She received her medical degree from Bangalore Medical College, India and did her Ophthalmology residency training and obtained the Membership of the Royal College of Ophthalmologists in London, and the fellowship of the Royal College of Surgeons in Edinburgh in the United Kingdom. She obtained a PhD, focusing on molecular genetics of eye diseases and completed a fellowship in pediatric ophthalmology at the University of Iowa. Following this she went to the University of California in San Francisco for another fellowship in medical genetics. Her research interests include the molecular genetic studies of ophthalmic diseases and ophthalmic manifestations in Ras/MAPK pathway syndromes. She has won the Western Scholar and Henry Christian Award for Excellence in Research from American Federation of Medical Research. She is leading the “Ocular Predictive Heath Initiative” project with a goal of establishing a database and DNA bank for inherited and complex eye diseases with genetic etiology at Emory.

## Strabismus

*J Bronwyn Bateman and Sherwin J Isenberg*

This article is a revision of the previous edition article by J Bronwyn Bateman and Sherwin J Isenberg, volume 3, pp 3228–3240.

### 139.1 INTRODUCTION

Strabismus, or ‘squint,’ is a misalignment of the visual axes of the eyes and occurs commonly. It may be termed ‘lazy’-, ‘wall’-, or ‘cross-eyed’ by the lay population. Nomenclature and classification systems are based on the amount (measured in prism diopters); direction of the deviation – horizontal, vertical, or torsional; laterality of deviating eye; frequency; age of onset; and the amount of deviation in the different fields of gaze (comitance or concomitance). The deviation can be latent (phoria; see below) or intermittent, both of which are based on fusional or binocular capabilities of the individual or, alternatively, it can be constant (tropia). The monofixation syndrome, a subset of strabismus defined as a small deviation (usually 10 prism diopters or less), may not be evident on external inspection and is associated with reduced but measurable fusion (binocularity; use of the two eyes together). Strabismus may be categorized on the basis of the age at onset of the deviation: ‘infantile’ is generally defined as occurring in the first 6 months of life, and ‘acquired’ develops at any age thereafter. Typically, as opposed to cranial nerve palsies or restrictive disorders such as dysthyroid ophthalmopathy, deviations that develop in childhood do not vary substantially in different fields of gaze (comitant or concomitant) such as right/left and up/down. The appearance of strabismus with aligned visual axes, as commonly occurs in infants and young children with epicanthal folds, is termed pseudostrabismus. Additionally, facial configuration may result in the appearance of strabismus even if the eyes are normally aligned.

Most forms of developmental delay are associated with a higher incidence of strabismus. Some forms of strabismus are associated with cranial nerve aplasia/malinnervation.

### 139.2 INCIDENCE AND PATHOPHYSIOLOGY

Strabismus occurs in 1.3–5.7% of all children (1–6). In some studies, strabismus occurs more frequently in females (7,8) and, in others, it occurs equally in males and females (9). For unknown reasons, normal males

have a stronger ability to maintain ocular alignment (10); evolutionary pressures may have favored human males with better binocularity.

Although refractive error is a variation of normal and has a genetic component, it is not a single gene phenotype. Both myopia (nearsightedness) and hyperopia (farsightedness) are important risk factors for the development of strabismus. The pathophysiological basis(es) of most cases are poorly understood. Clustering in families has been noted by many authors and dates to Hippocrates, who commented:

*‘We know that bald persons descend from bald persons; blue-eyed persons from blue-eyed persons and squinters from squinters, at least in the majority of cases’ (11).*

### 139.3 CLINICAL BACKGROUND

Historically, strabismus has been divided into phorias and tropias. A tropia is a ‘manifest’ deviation that is evident under binocular conditions (both eyes uncovered). Horizontal deviations are termed exotropia or exophoria (divergent), and esotropia or esophoria (convergent); vertical deviations are described as hyper- or hypotropias or phorias. As most individuals with strabismus have one eye that has better vision than the other, the deviating or non-fixating eye is designated. The horizontal and vertical deviations are quantified in prism diopters; a cyclotropia in which one or both eyes are torsionally deviated is measured in degrees. Horizontal and vertical deviations may be intermittent; namely, the strabismus may be evident at one moment but not another. A phoria is a deviation that develops under monocular viewing conditions; to identify a phoria or an intermittent (latent) strabismus (heterophoria), one eye is covered to eliminate the binocular stimulus to the central nervous system for ocular alignment. The deviation measured under the occluder is termed a phoria.

The causes of strabismus are poorly understood and the natural history differs in children compared to adults. Risk factors for the development of the most common forms of strabismus – the non-paralytic and

non-mechanical form with an onset in childhood – include reduced visual acuity uni- or bilaterally, refractive error of one or both eyes, reduction of the fusional (binocular) capabilities, mental retardation, neurological dysfunction, muscle disorders, including hypertonicity and hypotonicity, and craniofacial dysostoses. Less commonly, the disease can result from cranial nerve paresis, mechanical restrictions of the extraocular muscles, malformations of extraocular muscles, or supranuclear gaze disorders; such deviations are usually incomitant (difference in deviation depending on the field of gaze).

Sharp (focused on the retina) visual acuity in each eye and ocular alignment in early childhood fosters the central development of fusion (binocularity). Glasses/contact lenses may be necessary for sharp vision. Fusion is the ability to integrate the images from each eye and is the basis of depth perception; it develops early in life, during the stages of central nervous system plasticity in infancy. Ocular alignment is maintained by these fusional mechanisms, primarily stimulated by images on the peripheral retina. Children younger than 8–10 years of age have the ability to ‘suppress’ one of the images; thus, they usually do not have diplopia or double vision as a result of the ocular misalignment. Under binocular conditions, an individual with suppression will use one eye only; in an individual with normal fusion, the brain combines the slightly different images from each eye into a three-dimensional image. If central or peripheral vision is reduced in one eye, the risk for the development of strabismus is increased with the affected eye (reduced vision) deviating. Thus, organic causes of decreased vision, such as an asymmetrical decrease in central vision due to genetic diseases (e.g. Best disease) increases the risk of strabismus, as do decreases in peripheral vision, as occurs in retinitis pigmentosa. Likewise, decreased vision in an eye due to amblyopia increases the risk for strabismus. Curiously, the very gradual development of strabismus in a disease such as progressive external ophthalmoplegia may not cause double vision; the eye with reduced vision may be ‘ignored’.

The common forms of strabismus develop in childhood; congenital reduction of vision is associated with the onset of exotropia in infancy or early childhood. Individuals with a bilateral reduction of central or peripheral vision, for whatever reason (genetic or environmental), may have reduced binocularity, which constitutes an independent risk factor for strabismus.

The refractive status of the eyes, although a variation of normal in most instances, is the most common risk factor for the development of strabismus and is determined by the curvatures of the cornea and lens as well as the axial length (size) of the globe. These anatomical parameters form the basis of hereditary risk factors for strabismus. Hyperopia (farsightedness) predisposes to the development of acquired esotropia in childhood because the hyperopic individual must accommodate (focus) to clear the blurred image; accommodation and convergence

are synchronous. Normally, accommodation and accommodative convergence occur primarily when viewing near targets. However, hyperopic individuals must exert higher levels of accommodation both at a distance and close by in order to see clearly, and an esotropia may develop. Since accommodation is greatest for close targets, the deviation may be largest in these instances. Additionally, asymmetric refractive errors between the eyes may result in unequal visual acuity with and without glasses/contact lenses, which, in turn, may cause reduced binocularity, suppression, and an increased risk of strabismus. All children with strabismus are at risk of developing amblyopia (poor monocular vision related to reduced stimulation of the monocular visual pathways of the central nervous system in childhood) in the deviated eye. Myopia (near-sightedness) is a risk factor for exotropia.

Developmental delay, mental retardation, neurological dysfunction, and muscular disorders, including hyper- and hypotonicity, regardless of the cause, increase the likelihood of developing strabismus. Children with cerebral palsy are particularly prone to ocular misalignment. The mechanisms are poorly understood and may be similar to that in normal individuals; in particular, the neurological process of accommodative convergence and fusional ability may be poorly coordinated, predisposing to misalignment of the visual axes.

Craniofacial configuration is primarily determined genetically, and the interpupillary distance may influence the risk for the development of strabismus; a wide interpupillary distance increases the likelihood of exotropia (12,13). Craniofacial configuration may give the appearance of strabismus (pseudostabismus) when there is normal ocular alignment and, conversely, individuals with strabismus may appear to have normal ocular alignment. Furthermore, individuals affected with any of the craniofacial dysostoses are at increased risk of strabismus on the basis of altered (increased or decreased) interpupillary distance, exorbitism (shallow orbit), and/or malformations of the extraocular muscles. Strabismus is very common in the Crouzon, Apert, and Pfeiffer syndromes and in craniofacial malformations associated with midline defects.

### 139.4 ISOLATED STRABISMUS

The causes of non-paralytic strabismus, the most common form of strabismus, are many, and no single mechanism, environmental agent, and/or gene defect, has been identified as causative. An OMIM assignment has been given to a presumed susceptibility gene [OMIM %185100. There have been many, generally older, reports regarding the heritability of the common forms of strabismus and several excellent reviews have been published (8,14–17). Studies of the genetic bases of strabismus are difficult for many reasons. The definition of abnormal has a major influence on the conclusions of any study and the criteria for assignment of

affected status are variable and subject to debate. Phorias, particularly exophorias, are common in the general population, and the criteria for normalcy have not been established. Further complicating the assessment, many studies are retrospective and some combine multiple forms of strabismus, which may have different bases. As the pathogenic mechanisms of some forms of strabismus are unknown, the current classification system may not correlate with the causes. Additionally, documentation of cycloplegic refraction (pharmacological paralysis of accommodative or focusing mechanisms) is often absent in studies, making interpretations unreliable. There have been few, if any, studies to support the concept that environmental factors influence strabismus. Thus, strabismus is common and large populations would be required for definitive studies.

The incidence of strabismus in different cultural and genetic populations has been investigated and results vary considerably (18). Minor (19) believed that the incidence of strabismus was lower in African Americans as compared to Caucasians; Grover and Yaukey (20) confirmed this observation in a study in the 1940s, and similar findings were reported more recently (21). Holm (22) found that the incidence of exotropia was similar in African Americans and Caucasians but reported that esotropia is uncommon. The incidence of exotropia and myopia has been shown to be higher in Asian Indian children than Caucasians in England (23). Exotropia may be more common in Asians (18), as the prevalence of exotropia is increasing in Hong Kong (24). In Hong Kong, there are more individuals with exotropia than esotropia (24); in the United States and the United Kingdom, there are more individuals with esotropia than exotropia (21,25,26). These differences may be related to myopia (nearsightedness).

Experienced clinicians concur that strabismus is a heterogeneous disease and clusters in families. Population studies support a hereditary component (Figure 139-1) with a prevalence in siblings of an affected individual ranging from 11% to 70% (2,3,7–9,26–35). Esotropia tends to have a higher incidence in siblings in comparison to exotropia (7,32). The familial aggregation is greater than the clustering of known risk factors for strabismus (32). Chimonidou and colleagues (36) studied a Greek population and found strabismus, by report, in 55% of family members; they studied siblings with strabismus and found that over 95% were concordant for the type of deviation. Simpson and Alleslev (35) studied 311 siblings of 291 affected children from the Registry for Handicapped Children and Adults from British Columbia, Canada and found that strabismus, central nervous system disease, and stillbirths were more common in siblings of the proband than in the general population. Most studies combine forms of ‘comitant’ strabismus, and the conclusions may be unreliable because of heterogeneity.

Although many pedigrees of families with strabismus have been published, conclusions are inconsistent.

**FIGURE 139-1** Two brothers born with esotropia. They also had a sister born with the same condition.

Landon (37) reported a four-generation family with esotropia with multiple affected members in each generation. Czellitzer (38) found consanguinity in 6% of the parents of children with esotropia compared to a mean of 0.65% in the general population, and postulated two recessive loci causing strabismus (7,38); however, Waardenburg (8) believed that no conclusions could be inferred because consanguinity was relatively high in that Prussian community. As strabismus is relatively common in the general population, individual pedigree analyses generally do not establish Mendelian inheritance.

Dahlberg and Nordlow (39) studied two populations and obtained historical information regarding strabismus in parents, grandparents, and siblings of randomly selected children with esotropia and, based on simple Hardy–Weinberg calculations, concluded that the disease was not caused by a single autosomal dominant or an autosomal recessive gene. On the basis of his pedigrees, Waardenburg (8) postulated a ‘chief gene which may be supported by mainly dominant accessory genes’. Francois (40) reviewed his personal experience with esotropia and reported four pedigrees with members affected with strabismus; on the basis of vertical transmission through three generations in all his families, he concluded that autosomal dominant inheritance with reduced penetrance accounted for the disease. He postulated that heterophorias and heterotropias were caused by variable expressivity and that a heterophoria that predisposes to strabismus might be the trait, with environmental factors such as refractive error significantly influencing the outcome or likelihood of developing the disease.

More recently, Dufier and colleagues (9) retrospectively studied the families of 195 individuals with isolated esotropia. They found an affected family member of the proband, by history or examination, in over 50% and vertical transmission from parent(s) to child in 35%. They performed segregation analyses assuming a frequency of 3% of strabismus in the general population and concluded that an autosomal dominant model with incomplete penetrance was most likely for esotropia and

that an autosomal recessive model was most compatible with esotropia with amblyopia. Such conclusions are not fully supported because the assignment of affected status was based on historical information for some individuals.

Maumenee and colleagues (41) studied over 170 families with at least one member with infantile esotropia; some were ascertained by a parent with the disease and others through a young proband. Segregation analyses were performed and supported a Mendelian codominant model for a common allele. The standard errors were large and the authors suggested the existence of etiological heterogeneity with autosomal recessive, autosomal dominant and non-genetic cases.

Studies of families ascertained on the basis of a proband with exotropia are infrequent. Waardenburg (8) reported 18 families with more than one member with exotropia; 13 exhibited vertical transmission from parent to child. He postulated autosomal dominant inheritance with reduced penetrance and Francois (40) provided support with additional pedigrees.

Schlossman and Priestley (26) studied 88 families with both esotropia and exotropia, adding some families to 'enrich' the data with 'pertinent cases'; the authors calculated segregation ratios and concluded that both esotropia and exotropia were autosomal recessive diseases with one in four individuals carrying the gene for 'strabismus'. The study is not recent and their database may not be representative of current populations.

In an extensive and careful study by Richter (34), the siblings and parents of patients (probands=697; total=1509) and children with strabismus (probands=136; total=344) were ascertained at the time of vaccination. She combined the forms of strabismus and found affected siblings in 20–30% if neither parent was affected, in 30–44% if one parent was affected, and in 33–50% if both parents were affected. Thus, recurrence risks are increased if a strabismic proband has affected parent(s) or siblings. In a series of large quantitative genetic studies, Mash, Spivey, Hegmann, and their colleagues studied ocular alignment and other parameters in a group of strabismic patients and their families from the US state of Iowa. The studies assessed the heritability of ocular measurements that predispose to the development of strabismus. In 1972, Niederecker, Mash, and Spivey (10) found that parents of probands with either esotropia or exotropia had less ability to maintain ocular alignment (fusional amplitudes) than controls. In a subsequent study, Mash, Hegmann, and Spivey (42) found that certain vergence amplitudes (ability to align the eyes and fuse disparate images with artificial, prismatic misalignment) had higher heritability values than others and differed significantly among the strabismus populations. In 1974, Hegmann, Mash, and Spivey (43) performed regression analyses and calculated heritability for interpupillary distance; angle kappa  $\kappa$ , which is partially responsible for pseudostrabismus (the appearance of strabismus); and refractive error, including astigmatism,

in the families of affected individuals. They calculated a heritability estimate for interpupillary distance of 0.65 and for angle kappa  $\kappa$  of 0.44 but were unable to infer conclusions regarding refractive error because of large standard deviations. In a subsequent assessment of ocular deviation and the relationship of accommodative convergence to accommodation (AC/A ratio) (42), they found that ocular alignment (esodeviation or exodeviation) tended to be consistent within a family with substantial heritability from the female parent at 0.42. They also found that relatives of patients with esodeviations tended to have esodeviations and relatives of patients with exodeviations tended to have exodeviations; for unknown reasons, the mother's ocular alignment correlated best with that of the offspring. They calculated the heritability of the AC/A ratio at 0.38. These studies confirmed a heritable component, and support the concept that both anatomic features and binocular fusion (central nervous system) are factors in the development of strabismus.

A large family with accommodative esotropia was studied using linkage analysis, assuming an autosomal recessive model; linkage to a presumed susceptibility locus at 7p22.1 was demonstrated with a convincing log of the odds (statistical estimate of likelihood of genes being close to each other on a chromosome) score of 4.51 (44). Other families in the study did not demonstrate linkage to this region.

The monofixation syndrome or microtropia is a subset of strabismus characterized by a small deviation of ocular alignment associated with reduced fusion or binocularity; amblyopia may occur. Lang (45,46) studied over 20 families with at least one affected member and concluded that there was a hereditary tendency; he did not postulate a Mendelian pattern. Cantolino and von Noorden (47) studied 20 patients and family members and identified multiple asymptomatic relatives. They concluded that the hereditary pattern was most consistent with multifactorial inheritance on the basis of the absence of any 'simple Mendelian' pattern; six pedigrees were published and all showed vertical transmission of microtropia, strabismus, or both.

Twin studies further support the concept of a hereditary component predisposing to the development of strabismus. Waardenburg (8) combined previous reports of esotropia in twins with his cases and found the concordance rate of strabismus in monozygotic pairs to be approximately 80% (69 sets) and in dizygotic pairs to be approximately 12% (101 sets); he had no examples of exotropia in twins and there are few in the literature. The famous conjoined twins, Chang and Eng, each had exotropia (48). DeVries and Houtman (49) studied 17 pairs of monozygotic twins in which the proband developed esotropia within the first year of life and found concordance in eight. Rubin and colleagues (50) queried 50 ophthalmologists and compiled results on 22 sets of twins in which the proband had exotropia, and 122 pairs

in which one had esotropia; concordance was 77% in the monozygotic sets and 50% in dizygotic for exotropia and 75% in monozygotic and 53% in dizygotic for esotropia. Heritability was 0.54 for exotropia and 0.47 for esotropia. The authors analyzed esophoria and exophoria (deviation only present in the eye under an occluder and, thus, under monocular testing) separately and found the concordance to be relatively low for both (50). Richter (34) also studied strabismus (combining esotropia and exotropia) in twins and found concordance in 11 of 12 monozygotic pairs and 7 of 27 dizygotic pairs; based on all studies, including the twins, she concluded that strabismus was multifactorial. Hofstetter (51) studied 25 pairs of monozygotic twins and found a correlation coefficient of 0.67 for the AC/A ratio, which was higher than between pairs or families. Matsuo and colleagues (52) found the strabismus phenotype to be highly concordant in a relatively large study of Japanese twins. If genetic factors alone account for strabismus, the concordance of monozygotic twins should be 100%; conversely, if environmental influences alone cause the condition, 4% or less (the prevalence in the general population) of the dizygotic twin of an affected individual should be similarly affected.

Although no single intrauterine environmental agent has been shown to cause strabismus, the incidence of both esotropia and exotropia is higher in offspring of mothers who smoke during pregnancy; low birth weight was an additional risk for strabismus (21).

In conclusion, previous studies of the genetic bases of strabismus are difficult to interpret. Isolated strabismus is a common trait in the general population, and the causes are poorly understood. Without doubt, all forms of strabismus, esotropia, exotropia and the monofixation syndrome cluster in families, and there is limited evidence in support of an environmental basis aside from those factors that cause or predispose to mental retardation. However, strabismus does not appear to develop as a

result of a single gene mutation. Some authors have postulated polygenic or multifactorial models (34,53–55) with a ‘threshold’ level of many factors, such as interpupillary distance, fusional ability, and refractive error, with strabismus becoming manifest if the individual has a combination of abnormalities.

Genetic counseling to an individual or parent of a child with strabismus regarding recurrence risk is not precise unless the ocular misalignment is secondary to an identifiable genetic disease. Although strabismus is common, recurrence risks have not been rigorously established. Cross (53) estimated the recurrence risk for a siblings of an affected individual to be 14–30% if neither parent was affected, 30% if one parent was affected, and 30–50% if both parents were affected, based on the work of Richter (34) and Czellitzer (7,38).

### 139.5 SINGLE GENE DEFECT DISORDERS

#### 139.5.1 Duane Anomaly/Syndrome

The Duane anomaly/syndrome (DURS1; OMIM %126800) (DURS2; OMIM %604356), initially described in 1905 (56), is caused by aplasia/hypoplasia of the sixth cranial nerve nucleus (57) with aberrant generation of the third nerve in many, but not all, cases (58). A peculiar combination of ocular motility anomalies is evident with narrowing of the vertical palpebral fissure on adduction (when the affected eye is directed toward the nose) and widening of the palpebral fissure on abduction (toward the temple); the ability of the eye to abduct is often reduced (Figure 139-2) (58). While many Duane anomaly/syndrome patients have no strabismic deviation in primary (ahead) gaze, other patients have an exotropia or esotropia and may compensate for the deviation by turning the head to achieve fusion. Subtypes, based on the strabismus, have been described but most clinicians

**FIGURE 139-2** Duane retraction syndrome. (A) Head turn to achieve fusion. (B) Narrowing of palpebral fissure in abduction.

currently describe the specific findings rather than categorize. Curiously, the profound atrophy of the lateral rectus (abducens) found in chronic VIth nerve palsy is not evident in Duane anomaly/syndrome (59a).

Although the isolated Duane anomaly disorder is usually sporadic, autosomal dominant inheritance occurs (DURS1)(60–64) in approximately 10% of cases (65). More than one of the clinical subtypes may be evident in a single family (60). Bilaterality occurs in 12–16% of both sporadic and autosomal dominant cases (60,66,67). A region (DURS1) (OMIM #126800) at 8q13 has been supported by several reports of chromosomal rearrangements (68–70).

A second locus (DURS2) (OMIM #604356) was mapped in a single large family (60) to 2q31 (71) and confirmed in additional families (72,73a). Seven mutations in the gene, *chimerin1* (*CHN1*; \*118423) that normally encodes two protein products,  $\alpha$ 1-chimerin (n-chimerin) or, a result of alternative splicing,  $\alpha$ 2-chimerin, a Rac guanosine triphosphatase-activating (RacGAP) signaling protein were reported in autosomal dominant cases (DURS2-DRS); all mutations result in abnormal  $\alpha$ 2-chimerin products with a gain-in-function (19a). These authors also reported that expression of mutant  $\alpha$ 2-chimerin constructs in chick embryos resulted in failure of oculomotor axons to innervate their target extraocular muscles (19a). Additional mutations have been reported (74a) and clinical variability within a family has been documented (75a).

In the sporadic cases, there is a preponderance of females (67). Concordance in monozygotic twins has been reported (76) with mirror-like laterality; however, discordance in monozygotic twins also has been documented (77). A germinal mutation in the *CHN1* gene is not a common cause of sporadic Duane anomaly/syndrome (19b). Systemic anomalies associated with sporadic Duane anomaly/syndrome include upper extremity anomalies (78), radial ray deformities (79,80), cardiac defects (81), deafness (79), blepharophimosis (82), and pseudotumor (83).

The Athabaskan brain stem dysgenesis syndrome/Navajo brain stem disorder/Bosley–Salih–Alorainy syndrome (#601536), autosomal recessive disorders of brain stem dysgenesis and characterized by global developmental delay, autism spectrum disorder, facial weakness, horizontal gaze palsy, deafness, central hypoventilation, seizures, and vascular malformations of the internal carotid arteries and cardiac outflow tract are caused by mutations in the *HOXA1* (\*142955) gene (84a). Affected members of several Middle Eastern families had Duane anomaly/syndrome and some had developmental delay, deafness and external ear defects (Bosley, 2009). Germinal mutations of the *HOXA1* gene are not common in Duane anomaly/syndrome.

Horizontal gaze palsy and early-onset, progressive scoliosis (#607313) is an autosomal recessive form of progressive external ophthalmoplegia (Dretakis, 1970;

66a, 86a)) and was mapped to 11q23-25 (66a). Nystagmus and synergetic convergence, asynchronous blinking and nystagmus may be evident (87a). The gene was mapped to 11q23-25 (66a) and mutations found in the *ROB3* gene (\*608630) (66b,74b,87a,88a,89a).

Wildervanck syndrome (OMIM #314600) consists of hearing loss, Klippel–Feil anomaly (fused cervical vertebrae), and Duane syndrome (90); it usually occurs in females and may be multifactorial and/or polygenic (91). Deafness may occur (92). Its basis is not known.

Duane anomaly/syndrome, deafness, and the Klippel–Feil syndrome can be inherited together as an autosomal dominant trait (63). An autosomal recessive form has been reported (93).

When associated with blepharophimosis (blepharophimosis/ptosis/epicanthus inversus (#110100) (94a,95b), mutations of the winged helix/forkhead transcription factor gene (*FOXL2*) (OMIM \*605597)) gene have been the basis (3a,61a,72a,82,96a,97a,b,c,98a,99a,c,100a).

The Duane-radial ray (DRRS) (OMIM #607323)/Okishiro (OMIM #607323)/IVIC syndrome (OMIM 147750) shows autosomal dominant inheritance, and consists of Duane syndrome (unilateral or bilateral) (89) and forearm anomalies ((78,80,81,88,89,96,101,102,103,104a); Temtamy 1978; (94d)). Not all affected individuals have Duane syndrome (105); some have renal disease (88,106), dental anomalies (94d), hearing loss (89c), thrombocytopenia (89c,107a) and anal stenosis (80). Colobomata (88) and optic nerve hypoplasia (102) have been reported. Multiple mutations of the gene encoding a zinc finger transcription factor *SALL4* (OMIM \*607343) have been reported to cause the disease (85, 85a,89,94c,105,106a,108,109,110a). Although there is clinical overlap between the DRRS syndrome and the Holt–Oram syndrome (OMIM #142900), the genetic defect is different; the mutated gene defect in the Holt–Oram syndrome is the *TBX5* (OMIM \*601620) which produces a DNA-binding protein that controls cellular differentiation.

The Townes–Brocks syndrome (#17480) is characterized by renal, aural and thumb anomalies and syndactyly, and its genetic basis is a mutation of *SALL1* (\*602218), containing a DNA-binding zinc finger domains and alanine- and glutamine-rich domains that are commonly found in transcription factors (105a); the disease is usually caused by premature codon termination with haplotype insufficiency. Less common manifestations include Duane syndrome (111a), chorioretinal colobomata (111a), iris Brushfield spots (111a), epicanthal folds (111a) facial nerve palsy (111a), deafness, hypothyroidism, gastroesophageal reflux, vaginal aplasia with bifid uterus, cryptorchidism, bifid scrotum without hypospadias scrotalis, hypoplasia of the corpus callosum, kyphosis, cardiac malformations and umbilical hernia (32a,49a,68a,95a,111a,112b,113a,114a); radial bone involvement has not been published and distinguishes the

**FIGURE 139-3** Congenital fibrosis syndrome. Chin is elevated to permit fusion with the eyes pulled downward by fibrotic inferior rectus muscles. Ptosis is present.

syndrome from the DRRS (OMIM #607323)/Okiihiro/IVIC syndrome (OMIM 147750). The possibility of a maternal anticipation has been raised (114a). Significant intra- and interfamilial variability has been documented.

### 139.5.2 Congenital Ocular Fibrosis Syndrome

Congenital ocular fibrosis syndrome, originally described in the late 1800s (115), is a group of diseases caused by inelasticity or fibrosis of some or all of the extraocular muscles. Affected patients usually have bilateral ptosis (droopiness of the eyelids) and strabismus with significant restriction of movement of the globes. The strabismus may be progressive (116). Many families with the autosomal dominant (111,117,118) and the autosomal recessive (119,120) forms have been described. Usually, both eyes are deviated downward due to more severe fibrosis of the inferior rectus muscles (Figure 139-3). Based on surgical findings, the muscles are fibrotic and may insert in an anomalous position (121); treatment is surgical (121,122). The disease, in at least one phenotype, is caused by absence of the superior division of the oculomotor (III) cranial nerve (73,58). This condition has been reported in association with the Prader-Willi syndrome (#176270) (59), Möebius syndrome (multiple cranial nerve palsies) (OMIM %157900) (123), optic nerve hypoplasia (123), Marcus-Gunn jaw winking (synchronous movement of the lid with chewing and/or jaw movement) (OMIM 154600) (124,125), and nervous system anomalies including agenesis of the corpus callosum, colpocephaly, hypoplasia of the cerebellar vermis, expansion of the ventricular system, pachygyria, encephalocele, hydrancephaly and spinal stenosis (124,126).

Congenital ocular fibrosis syndrome is usually inherited as an autosomal dominant trait (86,111,117,118)

(CFEOM1; OMIM #135700) (CFEOM3; OMIM %600638), with complete penetrance (CFEOM1) and variable expressivity; two forms were established on the basis of mapping to different chromosomes. Mapping of the autosomal dominant form by linkage analysis supported at least two loci, one on chromosome 12 (CFEOM1) (127) and another on chromosome 16q24.2–q24.3 (CFEOM3) (128). The expressivity is described as more variable in CFEOM3 (128). A recessive form (CFEOM2) (OMIM #602078) has been described and has been mapped to 11q13 (120); further genetic heterogeneity may exist (119).

The CFEOM1 form is caused by mutations of the gene entitled kinesin family member 21A (*KIF21A*) (OMIM \*608283) on chromosome 12q12. The protein product is a microtubule-dependent motor protein involved in the transport of cellular components along axonal and dendritic microtubules and multiple mutations in the coiled-coil domain have been described (116,117,123,129,130). A form with reduced penetrance has been mapped to this region (127) and mutations of the *KIF21A* gene reported (130). Thus, depending on the mutation, the heterozygote and the homozygote may exhibit clinical manifestations. Mutations of the *KIF21A* gene also may cause congenital ocular fibrosis syndrome associated with Marcus-Gunn jaw winking (125).

The second autosomal dominant form (CFEOM3) is less common and may be associated with reduced penetrance (128); it is a distinct form as it maps to chromosome 16q24.2–q24.3 (128,131). Some families with the CFEOM3 phenotype have mutations of the *KIF21A* gene (130).

Most cases of the autosomal recessive form are caused by mutations of the gene *ARIX/PHOX2A* (OMIM \*602753), on chromosome 11q13.3–q13.4, which regulates transcription of neurotransmitters such as the catecholamine biosynthetic genes. The families are clustered in the Middle East and several mutations have been reported (132,133).

A second autosomal recessive form (OMIM %609428) (Tukel syndrome) with ulnar hand deformities has been mapped to chromosome 21q22 in a large, consanguineous Turkish family (134).

The documentation of different genes causing CFEOM underscores the importance of a categorization based on the gene and specific mutations.

### 139.5.3 Möebius Syndrome

Initially described in the 1880s (135–137), individuals with the Möebius syndrome (OMIM %157900) usually have bilateral sixth and seventh nerve palsies; the sixth nerve palsies cause reduced abduction of the eyes and a large esotropia that may be difficult to treat surgically. The disease is a brain stem disorder (138,139) and hypoplasia of the sixth, seventh, and/or twelfth nerve palsies have been reported (95,114,140). Although ptosis may

be evident, abnormal neonatal sucking is usually the first symptom.

In a large study (139), Duane syndrome was evident (34%) and other manifestations such as hypesthesia of the cornea and face, autism, tongue hypoplasia, dysarthria with palatal and pharyngeal involvement other craniofacial abnormalities such as epicanthal folds, flattened nasal bridge, micrognathia, high-arched palate, external ear defects, dental anomalies and hypertelorism; malformations of the extremities, brachydactyly, clinodactyly, syndactyly, metacarpal abnormalities, pes planus, hypoplasia of the lower legs, talipes equinovarus, and arthrogryposis were common. Möebius may be associated with the Poland syndrome (141).

The disorder may be inherited in an autosomal dominant pattern (62b,142–144,145a) and has been reported to be concordant in twins (146) who had absent facial nerves at autopsy. Autosomal recessive inheritance also has been reported (142). A gene (MBS1) for the disorder has been mapped to 13q12.2–q13 and multiple chromosomal rearrangements have been reported (104,144,147–149). The disease has been transmitted vertically in a family, with affected members having a reciprocal translocation between chromosomes 1 and 13 (144). Linkage analyses have mapped genes for the disease to 3q21–q22 (112) and 10q21.3–q22.1 (150). Intra-uterine environmental agents such as thalidomide may cause the disease (151).

### 139.6 STRABISMUS ASSOCIATED WITH OTHER OCULAR DISEASE

Any genetic disorder that decreases vision in one or both eyes, particularly if asymmetrical, may be associated with strabismus. If the basis of the reduced vision is hereditary, the strabismus is a secondary effect of the gene defect. Thus, any genetic disease in which vision may be reduced is associated with a higher incidence of strabismus. Examples of such diseases include colobomatous microphthalmia, which may be inherited as an isolated

autosomal dominant disorder or be associated with single gene multisystem disease or chromosomal rearrangements (Figure 139-4), pediatric cataracts, which may be inherited as an autosomal dominant or recessive, or X-linked trait or be associated with multisystem or metabolic disorders, and retinal degenerations.

### 139.7 STRABISMUS ASSOCIATED WITH MULTISYSTEM DISEASE

#### 139.7.1 Mental Retardation

Any disease, regardless of its etiology, associated with mental retardation will have a higher incidence of strabismus – presumably related to either a reduced ability to achieve binocularity or an elevated AC/A ratio (see above) of the eyes. The mechanisms of strabismus in such individuals are poorly understood, but the increased incidence, although poorly documented, is readily apparent to ophthalmologists. As many disorders caused by single gene defects and chromosomal anomalies are associated with mental retardation, no single disorder is included in this chapter.

#### 139.7.2 Neuromuscular Disorders

Individuals with neuromuscular disorders, particularly cerebral palsy and ataxia, are commonly affected with strabismus. The cause is poorly understood but may be related to abnormalities in coordination that may alter accommodative convergence, fusional convergence, or both; such individuals may have difficulty in initiating and/or maintaining ocular alignment.

#### 139.7.3 Craniofacial Anomalies

The craniofacial synostoses are a group of disorders that are characterized by the premature closure of one or more cranial sutures (Figure 139-5). Such premature closure frequently alters configuration, including depth and

**FIGURE 139-4** Colobomatous microphthalmos. (A) Eyes are small and esotropic. (B) Defect in inferior iris extends to involve the optic nerve.

of the bony orbit, the relationship of the eye to the origin of the extraocular muscles at the apex of the orbits, and the distances between the pupils and the inner and outer canthi. Strabismus, shallow orbits with exposure of the cornea in some cases, or papilledema with subsequent optic atrophy may occur in any craniofacial anomaly; reduced vision increases the risk for strabismus. An exotropia commonly occurs; presumably because of the altered and divergent axes of the globe with respect to the orbit. Incomitance (different amount and/or direction of the ocular axes in different directions of gaze) is frequently encountered with variability of the deviation depending on the field of gaze; a V pattern exotropia is the most common form of 'incomitance', with the eyes diverging more in upward than downward gaze. Crouzon disease, Apert syndrome, and Pfeiffer syndrome, all of which are inherited in an autosomal dominant pattern, are commonly associated with strabismus for the aforementioned reasons; additionally, these disorders are associated with structural abnormalities of the extraocular muscles, including fusion, absence, or anomalous insertions of muscles (152,153). Other forms of premature closure of the sutures also are associated with an increased incidence of strabismus.

Most craniofacial dysostoses are caused by mutations of genes in the fibroblast growth receptor family and are tyrosine kinase receptors (145). The ocular features are similar in all and include shallow orbit with intermittent prolapse of the globe anterior to the lids, astigmatism, amblyopia, abnormal (fused or absent) extraocular muscles, and strabismus (100,153–155). The extraocular muscles can be absent, fused, and/or inserted on the globe in an abnormal location, resulting in a mechanical basis for at least some of the cases of strabismus (153). Stretching or traction on the optic nerve is a possible cause of decreased vision. However, hydrocephalus can lead to papilledema and optic atrophy (156).

**FIGURE 139-5** Child with craniofacial anomaly and exotropia.

Crouzon disease (CFP1) (OMIM #123500) has craniosynostosis as its major manifestation, and Apert syndrome (Apert) (ASC1) (OMIM #101200) is characterized by craniosynostosis and syndactyly of the hands and feet; both are caused by mutations of the. Individuals with Pfeiffer syndrome (ACS5) (OMIM #101600) have craniosynostosis and broad, short thumbs and large toes (157), and those with Saethre–Chotzen syndrome (OMIM #101400) have craniosynostosis, symmetrical syndactyly, ear anomalies, and a characteristic facies (158,159); blepharophimosis may be a feature (160).

Mutations of fibroblast growth factor receptor-2 (*FGFR2*) (OMIM \*176943) on chromosome 10q26 may cause Crouzon disease (161,162) as well as Apert (163), Pfeiffer (162) and Saethre–Chotzen (47,164) syndromes. The mutations causing Apert syndrome occur in a specific region of the *FGFR2* gene, and most cases represent one of the two common mutations (163,165,166) at the site.

Pfeiffer syndrome (OMIM #101600) is usually caused by heterozygous mutations of the *FGFR1* gene (\*136350) (75,167) on chromosome 8p11.2–p11.1, the *FGFR2* gene (OMIM \*176943) on chromosome 10q26.13 on chromosome 4p16.3; however, mutations on the *FGFR3* gene on chromosome 4p16.3 also may cause the phenotype of Pfeiffer syndrome. The identical mutation in the *FGFR2* gene can result in either Crouzon disease or Pfeiffer syndrome (162) (above), providing evidence that genetic modifiers influence the phenotype.

Although heterozygous mutations of the *FGFR3* (OMIM \*134934) gene, on chromosome 4p16.3, usually cause dwarfing syndromes such as achondroplasia (97), hypochondroplasia, and thanatophoric dysplasia; Muenke coronal craniosynostosis, lacrimoauriculodentodigital (149730) syndrome, Levy–Hollister syndrome, and the camptodactyly, tall stature, scoliosis, and hearing loss syndrome have been reported, Crouzon disease associated with acanthosis nigricans may be the phenotype (161a,110,89b). The mutation causing amino acid substitution Pro250Arg amino acid substitution in the *FGFR3* gene (97) in autosomal dominant craniofacial syndromes is similar to the mutation causing Apert syndrome in *FGFR2* and Pfeiffer syndrome in *FGFR1*.

Individuals with the Saethre–Chotzen syndrome (OMIM #101400) usually have mutations of the *TWIST1* gene (*TWIST1*) (OMIM \*601622) (47,94b, 112a,164,168,169) on chromosome 7p21, which encodes a nuclear transcription factor protein; less commonly, mutations in the *FGFR2* and *FGFR3* (above) cause the clinical features (47,164). A form with blepharophimosis is caused by a mutation in the *TWIST* gene (170).

Other craniofacial anomalies are associated with strabismus including clefting syndromes, frontonasal dysplasia, and the holoprosencephaly sequence.

Mandibulofacial dysostosis or the Treacher Collins–Francheschetti (TCOF) (OMIM #154500) syndrome, is a disorder of craniofacial development and is characterized

by malar and mandibular hypoplasia, downslanting lid slant, microtia, macrostomia and a defect in the outer third of the lower lid including absence of the lateral canthal tendon (171–175). Conductive hearing loss and cleft palate may be evident (176). Expression is variable (175,177). ‘V pattern strabismus’ (incomitant deviations) is common in this autosomal dominant disease (178). Additional ocular features include absence of the lacrimal puncta, congenital cataracts, uveal colobomata, and microphthalmia (67,178–180). The disease is caused by mutations of the treacle gene (*TCOF1*) (OMIM \*606847); the protein product is involved in ribosomal DNA gene transcription (181) and located on chromosome 5q32–q33.1. Multiple mutations have been described (176,182–186) and some regions appear to be ‘hot spots’ (184).

The Waardenburg syndromes are associated with pseudoesotropia. The disorders consist of lateral displacement of the medial canthi (dystopia canthorum); confluent eyebrows; partial depigmentation of the eyes, hair, and skin; and congenital deafness. Sensorineural hearing loss and heterochromia iridium are the two most diagnostic features (187). Because of the lid configuration, the eyes may appear to be esotropic (pseudoesotropia) despite alignment; approximately 20% have true esotropia (188).

Multiple forms have been described (188). The most discriminating clinical features include the inner intercanthal distance, which gives the appearance of esotropia (pseudoesotropia), philtrum length, lower facial height, and nasal bone length (189). There is a genotype–phenotype correlation with respect to mutation class and the coloration of the irides (190).

In Type 1 (WS1) (OMIM #193500), many mutations of the *PAX3* (OMIM \*606597) gene that activates the gene *MITF* (see WS2A) have been reported (191–193). Type 2AIA (WS2A) (OMIM #193510) does not have lateral displacement of the medial canthi (188); mutations of the gene *MITF* (OMIM \*15684), which encodes a basic helix-loop-helix (hHLH)-leucine zipper protein that influences the development of multiple cell types including neural crest-derived melanocytes and optic cup-derived retinal pigment epithelial cells, causes this form. The Type 2E (WS2E) (OMIM #611584) (194a)/Type WS4C (OMIM #613266) (124a)/Waardenburg-Shah syndrome (PCWH) (OMIM #609136) (18a) forms, like WS2A, does not have dystopia canthorum but may be associated with neurological signs is caused by heterozygous mutations of the *SOX10* (OMIM \*602229), a transcription factor with a DNA-binding motif high mobility group domain. Type 3 (WS3) (OMIM #148820) is characterized by the pigmentary anomalies, hearing loss/deafness and upper limb malformations and the basis is hetero- or homozygous mutations of the *PAX3* gene; dystopia canthorum and pseudoesotropia are found as occurs in WS1. The autosomal recessive (24a) and dominant (62a,127a) forms have been documented.

### 139.7.4 Chronic Progressive External Ophthalmoplegia

Chronic progressive external ophthalmoplegia is an acquired form of strabismus that may be associated with a mitochondrial myopathy and may be inherited in an autosomal dominant or recessive pattern. This disease overlaps with the mitochondrial myopathies, involving oxidative phosphorylation, including Kearns–Sayre which is caused by mitochondrial deletions (OMIM #530000). There is clinical overlap within this relatively diverse group of mitochondrial myopathies, and some mutations are somatic (180a). The five enzyme complexes (I, III, and IV) for oxidative phosphorylation are encoded by both nuclear and the mitochondrial DNA; complex II and complex V, adenosine triphosphate (ATP) synthase, are entirely nuclear.

In this group of disorders, ptosis and strabismus may develop at any age. The extraocular muscles become non-functional and the globe becomes progressively immobile; the eyes are usually misaligned. Although the patient may have diplopia (double vision), he/she may not as the onset is very gradual (personal experience). Additionally, retinal degeneration may develop and would be diagnosed on the basis of an abnormal electroretinogram. The retinal features are clinically variable and may precede the degeneration of the electroretinogram (94); evidence supports consistent changes in the retinal pigment epithelium in individuals with mtDNA defects (195).

The autosomal dominant forms are usually isolated (196) but may be associated with hypogonadism (197). The autosomal recessive form (198) (PEOB) (OMIM #258450) tends to be more severe and is usually associated with cardiopathy (199).

The bases are multiple; some families exhibit a Mendelian pattern of inheritance and others are compatible with mitochondrial inheritance (200).

One autosomal dominant form (PEOA1) (OMIM #157640) is caused by mutations of the gene (*POLG*) (OMIM \*174763), on chromosome 15q25, encoding DNA polymerase, gamma; the protein product is expressed in both the nucleus and the mitochondria. Mutations in the *POLG* gene disrupt the mtDNA by reducing the proofreading exonuclease activity of the enzyme, with accumulation of heteroplasmic levels of rare and recurrent point mutations in the skeletal muscle tissue and fibroblasts (201); multiple mutations in both the exonuclease domain (201) and other regions of the gene have been reported (202). Both hetero- (OMIM #157640) and homozygous mutations cause disease (203). Mutations in this gene also cause the form associated with hypogonadism (204).

The second autosomal dominant form of progressive external ophthalmoplegia (PEOA2) (OMIM #609283) is caused by mutations of the gene (*SLC25A4*; ANT; ANT1) (OMIM \*103220) encoding the predominant

mitochondrial protein ADP/ATP translocator, or adenine nucleotide translocator (solute carrier family 25 [mitochondrial carrier, adenine nucleotide translocator, member 4]); the gene is on chromosome 4q35. The reported clinical features are usually limited to the eye (205–207), but sensorineural hearing loss, thyroid disease, and an abnormal electromyogram have been described (205). Muscle weakness is not a feature. Few mutations have been reported (207–209).

The third autosomal dominant form (PEOA3) is caused by mutations (203,210) of the mitochondrial protein twinkle, the gene for which is entitled chromosome 10 open reading frame 2 (C10ORF2) (OMIM \*606075) and is on chromosome 10q24. The clinical features may be limited to the progressive external ophthalmoplegia or may include psychiatric disease with severe depression, hormonal dysfunction, cardiac disease, and generalized weakness (211) and may include dementia (9a); only ocular disease and muscle weakness may be evident (212). Multiple mutations have been reported (210).

The autosomal recessive form of chronic progressive external ophthalmoplegia, generally a more severe phenotype (204,213), is caused by mutations of the *POLG* gene that encodes DNA polymerase, gamma (202,203). Although individuals with Alper's syndrome, characterized by diffuse degeneration of gray matter, seizures, hepatic cirrhosis, and infantile demise, have mutations of the *POLG* gene, the only reported ophthalmological feature has been cortical visual impairment (214); strabismus has not been described.

The autosomal recessive disease SANDO is characterized by sensory ataxic neuropathy, dysarthria, and ophthalmoplegia (SANDO) (OMIM #607459) and is caused by mutations of the gene C10ORF2 (OMIM \*606075), above (215). However, the disease may be caused by mutations in the *POLG* gene (216,217). Thalamic lesions may be evident on MRI (218) and myopathy is not a feature. The mutations in the C10ORF2 gene (210,219) frequently result in deletions of mtDNA in the autosomal dominant form (211). In a sporadic case, heterozygous mutations were found in both the *POLG* and the C10ORF2 genes, a digenic mechanism (220).

Primary mutations of the mitochondrial DNA are not as common in progressive external ophthalmoplegia. However, deletions and primary mutations of the mitochondrial DNA are the bases of the Kearns–Sayre syndrome (KSS) (OMIM #530000). This disease is characterized by a progressive external ophthalmoplegia, cardiac disease and retinal degeneration (87). Endocrine disease is common (194,221). The bases are mitochondrial deletions and point mutations (222–224). A mutation in the mitochondrial tRNA for leucine (MTTL1) (OMIM \*590050), encoded by nucleotides 3230–3304, has been reported (225). A specific deletion has been reported with encephalopathy (226). These mitochondrial mutations may be inherited maternally (224) and, less commonly, paternally (227).

Progressive external ophthalmoplegia with myoclonus may be caused by mutations of the mitochondrial transfer RNA for lysine (encoded by mitochondrial nucleotides 8295–8364) gene (*MTTK*) (OMIM \*590060) (84,98,107). Thus, a mitochondrial mutation may be the basis of progressive external ophthalmoplegia and myopathy. A patient with myopathy, encephalopathy, sensorineural hearing loss, progressive external ophthalmoplegia, and retinopathy had a mutation of the mitochondrial tRNA for leucine is encoded by nucleotides 12266–12336 (228). Most reported mutations are somatic (98,225).

Some of the families with autosomal dominant inheritance of progressive external ophthalmoplegia may represent the congenital ocular fibrosis syndrome.

## 139.8 SUMMARY

Although increasing numbers of genetic are known to be responsible for strabismus, the common, pediatric varieties remain related to refractive errors, variations of normal.

# Retinoblastoma and the RB1 Cancer Syndrome

*A Linn Murphree, Robin D Clark, Linda M Randolph, Uma M Sachdeva,  
Dan S Gombos and Joan M O'Brien*

This article is a revision of the previous edition article by A Linn Murphree, Robin D Clark and Linda M Randolph, volume 3, pp 3241–3264, © 2007, Elsevier Ltd.

## 140.1 INTRODUCTION

A genetic syndrome is defined as a group of signs and symptoms that are characteristic of a specific individual or set of gene mutations. Retinoblastoma (Figure 140-1), an intraocular tumor of the developing retina, is the most often diagnosed malignancy of the *RB1* cancer syndrome, which results from mutations in the Retinoblastoma 1 (*RB1*) gene. The *RB1* syndrome is characterized by a lifelong predisposition to cancers of the retina, bone, soft tissue, skin and lung, amongst other tissues. Retinoblastoma can alternatively result from a somatic alteration of the *RB1* gene within the retina that has no heritable implications and which is not associated with a characteristic constellation of symptoms defining a syndrome. Regardless of its etiology, this solid childhood eye tumor has played a central role in illuminating the genetic mechanisms that regulate human cellular growth.

Retinoblastoma was the first tumor suppressor gene to be discovered and has defined the paradigm of the two-hit model of tumorigenesis (1). The *RB1* cancer syndrome exists when one allele of the retinoblastoma gene (*RB1*) is missing or inactivated in the germline, resulting in heterozygosity for the normal or wild-type *RB1* allele in all tissues. The development of each tumor focus, whether in the eye or elsewhere, then requires the loss or inactivation of the second *RB1* allele in a single retinoblast or other cell type, resulting in loss of heterozygosity and clonal expansion (Figure 140-2). Because the initial, predisposing *RB1* mutation, for genetic purposes termed 'M1', is present in all somatic cell types, multiple tissue types are at risk of tumor development following mutational events leading to loss of heterozygosity. Despite this general predisposition to tumor development, each individual tumor focus results from a separate second mutational event, termed 'M2'.

The initial M1 germline mutation may be inherited from either parent or may appear spontaneously during

embryonic development. Accordingly, the presence of mosaicism for M1 is a relatively common finding in the founder of a retinoblastoma pedigree. Regardless of whether M1 was inherited from a parent or occurred spontaneously, the presence of M1 in the germline constitutes the heritable retinoblastoma syndrome, as this mutation can be passed through the germline to offspring.

Alternatively, M1 may not exist in the germline, but may occur spontaneously in the developing retina. In this case, all other tissues, including the germline, do not possess *RB1* mutations and are not prone to tumor development. Intraocular tumors occur in these patients with acquisition of the second 'tumorigenic' mutation (M2) and are usually unifocal and unilateral. In these patients, both the *RB1* M1 and M2 mutations are not heritable and, therefore, are not passed on to offspring. The most common event associated with M2 in both heritable and non-heritable retinoblastoma is mitotic non-disjunction.

Because heritable retinoblastoma is associated with the *RB1* cancer syndrome and puts offspring at risk of retinoblastoma development, it is important for patients presenting with retinoblastoma to be seen by a clinical geneticist and to receive genetic counseling regarding the *RB1* mutation pattern underlying their disease.

The clinical geneticist must seek to answer two questions:

- (i) Is M1 present outside the eye in the patient or family being counseled, and
- (ii) If M1 is present outside the eye, when during the development of the embryo did it make its appearance and what tissues are affected?

The presence of retinoblastoma in both eyes can help answer those questions, since all patients with bilateral retinoblastoma have heritable disease. Genetic counseling for this disease would be simple and straightforward if all patients with unilateral retinoblastoma (Figure 140-3) had non-heritable disease. Unfortunately, that is not the

**FIGURE 140-1** Retinoblastoma is the grayish white mass that fills most of the vitreous cavity in this freshly enucleated and bisected eye. This tumor may fill the eye with little or no external sign except loss of vision in that eye, and that may never be noticed if the other eye is tumor-free. There is no evidence in this specimen of tumor extending outside the globe. Once the tumor has grown to this size, determining whether this tumor was of unifocal or multifocal origin is impossible clinically or histologically.

**FIGURE 140-2** Each of the white, round lesions is an independently arising intraretinal retinoblastoma in this image taken with a wide-angle retinal camera. The optic nerve is the orange disc just below the upper lesion. The fovea is the dark spot to the left of the optic nerve. The two larger lesions have recruited a blood supply. The faint small lesion at the lower right in the image is only 1.5 mm in diameter and has not recruited a blood supply. Each of these three lesions arose independently from the others as a result of inactivation of the normal allele at *RB1*. Multifocal retinoblastoma is clearly discernible only in early-stage disease, as in this image. Once the tumors grow to merge as a single tumor or intraocular ‘seeding’ of the tumor occurs, then multifocal disease cannot be separated clinically from unifocal disease.

case. Rather, 15 to 20 percent of patients with unilateral sporadic retinoblastoma possess a germline M1 mutation. Rarely, *RB1* mutations have been passed to offspring from people who never develop cancer in either eye. Alternatively, some patients with germline M1 mutations develop retinomas, a benign variant of retinoblastoma, or develop bone or soft tissue sarcomas without any ocular findings. These atypical presentations make it difficult

**FIGURE 140-3** Unilateral retinoblastoma in the right eye of a child whose pupils have been dilated pharmacologically. This is the classical ‘leukocoria’ or ‘cat’s eye’. The red reflex in the pupil in the child’s left eye can only be elicited with coaxial illumination from a direct ophthalmoscope or from the flash of a camera. A pen light will not elicit a red reflex. Small pupils will also prevent detection of this retinoblastoma.

to generate simple genotype–phenotype correlations, and patients without clear ocular findings may go undiagnosed for the *RB1* cancer syndrome. Identifying the *RB1* cancer syndrome in patients without bilateral retinoblastoma is one of the greatest challenges facing geneticists. The range of phenotypes associated with *RB1* mutations may be dependent on the specific molecular lesion present in the *RB1* gene. Certain mutations, such as the substitution of tryptophan for arginine at position 661, are associated with milder forms of disease, including unilateral benign retinoma and penetrance as low as 20%.

Since the discovery of *RB1* and its protein product pRb, significant research efforts have been undertaken to determine the role of pRb in the development of tumors and its intrinsic role in tumor suppression. Nevertheless, retinoblastoma itself is a very rare childhood tumor, with roughly 300–350 new cases diagnosed in North America each year. The majority of these patients are treated in one of five or six major retinoblastoma referral centers in the United States and Canada. It is not surprising, then, that most geneticists and pediatric ophthalmologists outside of these major retinoblastoma referral centers have little clinical experience with retinoblastoma patients and their families. Additionally, because referral of patients with suspected retinoblastoma comes from ophthalmologists, if a pediatric oncology unit is not widely recognized as an ocular oncology referral center, it will likely see and treat no more than five or six retinoblastoma patients annually. This is true of even the largest pediatric oncology programs. Most unilateral retinoblastoma patients are treated with primary enucleation for advanced disease and are not referred to a medical geneticist. Many pediatric ophthalmologists assume that sporadic unilateral retinoblastoma that presents relatively late in development, usually around two years of age, represents non-heritable disease. While this is often the case, this presentation is not sufficient to rule out heritable disease, due to the wide array of atypical presentations encountered with germline *RB1* mutations. For this reason, it is extremely important for all patients with retinoblastoma to undergo genetic testing, to determine

whether the patient harbors an underlying germline mutation that would put the second eye at risk of retinoblastoma, and the patient at risk of other life-threatening disease. The presence or absence of a germline mutation in a patient presenting with unilateral intraocular disease affects management of the eye, as isolated non-heritable cases often present late and are more frequently treated with enucleation. In contrast to this, cases with germline mutations are generally bilateral and patients present earlier with vision loss. These patients are treated most commonly with local therapy and chemoreduction. This has significant implications for patients, as chemotherapy and radiation, if required, have significant toxicities in these very young patients and may put these patients at higher risk of additional second tumor development.

## 140.2 INCIDENCE AND PREVALENCE<sup>1</sup>

Published incidence and prevalence figures for retinoblastoma assume that retinoblastoma represents a single disease. However, in 1971, Alfred Knudson separated this childhood tumor into heritable and non-heritable forms (1). Knudson's two-hit hypothesis, by which tumors develop from a single cell that has undergone two separate mutational events, M1 and M2, was based on the observed difference in the ages at diagnosis of bilateral and unilateral retinoblastoma patients and has provided the framework for our understanding of recessive tumor suppressor genes (1–4). For geneticists, the ultimate goal is to separate the two subgroups as distinct clinical entities. Unfortunately, incidence and prevalence figures are not available to compare the relative frequency of heritable and non-heritable retinoblastoma subgroups, regardless of their country of origin. This 'lumping' has tended to obscure the geographic differences in the relative frequency of the two subgroups.

The annual incidence of retinoblastoma, including both heritable and non-heritable subgroups, in North America is approximately 1 in 12,000–15,000 live births; in the Netherlands, the incidence is 1 in 17,000 (5). In Sweden and Finland, countries with comprehensive cancer registries and population data, the prevalence of retinoblastoma for the years 1958 through 1998 is reported at 11 cases for every million children younger than 5 years of age (6). The prevalence in Singapore is remarkably similar, at 11 cases for every million children in the under-5 age group (7).

Because most cases of heritable retinoblastoma result from new endogenous mutations, environmental influences have little role in their frequency and distribution (4). Geographic incidence differences appear to reflect

variance in the number of non-heritable, somatic cases. Sporadic, non-heritable retinoblastoma is more common in countries with a developing economy. Possible causes for this increased incidence of somatic retinoblastoma include socioeconomic, dietary, and infectious factors. Additionally, there is evidence to suggest that the real geographic differences in the relative incidence of heritable and non-heritable retinoblastoma are even larger than reported. The first evidence relates to the methods used to collect data. For example, the data for prevalence calculations in a study from Namibia came from children with retinoblastoma referred to and treated at a district or tertiary hospital (8). Among impoverished populations, many children with retinoblastoma die within the first few years of life from dissemination of their eye disease, due to lack of access to medical care. Therefore, prevalence data would tend to underestimate the frequency of disease, as relatively few patients are seen at the tertiary care centers where these studies are conducted. It is almost certain that some cases that are not seen at a tertiary or district hospital go undiagnosed. Nevertheless, the reported prevalence numbers in Namibia are twice those reported for more developed countries with lower poverty rates (6).

There are two additional factors that have an impact on the disparity in the distribution of retinoblastoma cases: world population distribution and birth rate. Because over 80% of the world's population lives in developing countries, the overall worldwide prevalence rates for retinoblastoma are likely to be significantly underreported due to the factors discussed above. Additionally, because the total fertility rate is significantly higher in developing nations relative to industrialized countries (4.0 relative to 1.4 children per woman) (9), statistically, there are at least 12 to 13 cases of retinoblastoma in developing countries for every case diagnosed in the developed world. Based on birth data from the 2002 Global Population Profile (10), and the incidence figures for the developed world, we estimate that approximately 1,000 new retinoblastoma cases occur each year in all of North America, Europe, Russia, Japan, Australia, and New Zealand combined, compared with 12,000 to 13,000 cases in developing countries.

## 140.3 THEORIES OF TUMORIGENESIS AND RB1

Nearly two decades ago, a group led by Weinberg, Albert, and Dryja cloned *RB1*, the first human cancer gene to be identified (11,12). Fung and coauthors published independent cloning of *RB1* three months later (13). The retinoblastoma tumor suppressor gene (*RB1*) is located on chromosome 13q14 and encodes the retinoblastoma tumor suppressor protein, pRB (14,15). Regardless of the genetic subgroup to which it may belong, retinoblastoma develops when an insufficient amount of the active form of pRB is available within a retinoblast to prevent repeated entry into the cell cycle (14–16). Inactivation

<sup>1</sup>Incidence is defined as the number of new cases of illness commencing, or of persons falling ill, during a specified time period in a given population. Prevalence is the proportion of persons with a particular disease in a given population at a given time. In referring to retinoblastoma, the proportion is usually expressed as the number of cases per 1 million children under the age of 5 years. Prevalence becomes an inaccurate measure of the occurrence of a disease if disease survival is low.

of pRB is universal in retinoblastoma cells, validating Knudson's two-hit hypothesis (17). Since its discovery, *RB1* has been shown to be a potent tumor suppressor in multiple cell types in addition to retinoblasts, and its central role in the suppression of human cancer is illustrated by the fact that almost all human cancers demonstrate pRB inactivation (18).

pRb plays a pivotal role in regulating the exit of cells from the cell cycle and in preventing continuous cell cycle progression. Significant research over the past two decades has helped to elucidate the molecular pathways responsible for suppression of cellular proliferation by pRb. pRb binds to pro-growth transcription factors of the E2F family, resulting in repression of the expression of their target genes. These E2F target genes encode enzymes responsible for DNA replication and nucleotide synthesis, as well as the growth-promoting cyclins A and E, and the proto-oncogenes b-Myb and c-Myc, amongst others (19–21). pRb also promotes G1 cell cycle arrest through the action of p27, a protein responsible for inhibiting the checkpoint cyclin-dependent kinase complexes that promote cell cycle progression at the G1/S transition. pRb promotes p27 activity by targeting the p27 inhibitor Skp2 for degradation by complexing it with the E3 ubiquitin ligase APC/C<sup>cdh1</sup>.

Because the intracellular deficiency of pRb protein is required for retinoblastoma development, the heterozygous genotype at *RB1* predisposes the retinoblast to become transformed into a cancer cell, but alone is insufficient for tumorigenesis. Transformation requires loss of function of both alleles at the *RB1* locus (22), and approximately 75 percent of retinoblastoma tumors demonstrate loss of heterozygosity (23) at chromosome 13 (24). As discussed, *RB1* analysis is now an essential part of the clinical evaluation of any child with unilateral, unifocal retinoblastoma, regardless of age at diagnosis. Meta-analysis of *RB1* mutations in 932 patients with retinoblastoma demonstrated that the predisposing mutation, M1, was most often a result of deletions and nonsense mutations, unlike other genetic diseases, in which missense mutations are most common (25). This analysis also identified 16 hot spots in the *RB1* gene that contained almost 40% of the total mutations observed. The remaining mutations were scattered throughout the length of *RB1*, but were most frequent in exons (26–32).

Examination of mutations by patients' country of origin identified two groups, demonstrating significant differences in the incidence of nonsense and splicing mutations (25). Valverde and colleagues noted a significant association between late age at diagnosis and splicing mutations. Their data suggest that there may be a genotype of *RB1* mutation that confers a delayed-onset phenotype. Most of the mutations in low-penetrance families were of three types:

- (i) Promoter mutations resulting in low expression of a normal *RB1* protein;
- (ii) Missense and in-frame deletions affecting non-essential sequence motifs, resulting in a partial inactivation of pRB that retains some functionality; and
- (iii) Splicing mutations leading to the reduction of normal messenger RNA splicing.

Lillington and coauthors employed comparative genomic hybridization (CGH) to identify chromosomal region alterations at sites other than 13q14 that are associated with histopathology, progression and patient outcomes (33). In an analysis of 49 tumors, chromosome imbalance was present in 96 percent of samples. In this series, as well as in a series from Germany (34), gains of 6p and 1q were the most frequent events. Alterations associated with metastasis included loss of 13q and 5q, while gain of 13q, monosomy of chromosome 16, and loss of 16q were more frequent in children in whom enucleation was performed at an older age (33). These authors found a significantly lower number of CGH alterations in eyes enucleated before one year of age relative to children enucleated at three years of age or above, with a median number of three chromosomal alterations found in the younger patients, as compared with 11 CGH changes in the older children.

#### 140.4 THE NATURAL HISTORY OF RETINOBLASTOMA TUMORIGENESIS

The process of tumorigenesis resulting in retinoblastoma involves the acquisition of several genetic alterations that occur sequentially (35,36). While the initiating event is the biallelic loss of *RB1* function, the subsequent genetic events, termed 'M3', which occur to accelerate tumorigenesis remain relatively unknown. Virtually all newly arising tumors that are smaller than 3 mm in diameter are perfectly round and symmetrical, the expected shape if all tumor cells were growing at the same rate (Figure 140-4). As clonal expansion proceeds, foci within the tumor clone show evidence of growth advantage. These foci develop into rapidly growing 'nodular excrescences' on the surface of the previously symmetric tumor (Figure 140-5) (37). Although there is no clearly documented connection between the ophthalmoscopically-observed focal growth changes in retinoblastoma tumors and specific chromosomal changes within the tumor, we know that, with time, complex chromosomal aneuploidy and associated genetic changes known to contribute to progression of malignancy take place within the tumor (38). Most of these changes involve loss of additional cancer suppressor loci or duplication of oncogene sequences. Regions of commonly observed chromosomal gains included in M3 include 6p22 and 1q31–2 (23). Candidate genes located in the amplified regions of 6p include the chromatin remodeling factor and histone chaperone protein DEK and the transcription factor E2F3 (39). DEK functions as a proto-oncogene through inhibition of apoptosis and promotion of cellular proliferation and de-differentiation

**FIGURE 140-4** Early intraretinal tumors are round because all cells are identical daughter cells of the original retinoblast that, by chance, developed M2, and was transformed into a retinoblastoma cell. No M3 events that bestow clonal growth advantage are yet manifest in this lesion. In the new international grouping system, this eye would be classified as group A disease. The tumors are 3 mm in size or less, and are further than 1.5 mm from the fovea and 3 mm from the optic nerve head (see Table 140-2).

(40–42). Its over-expression is also associated with inhibition of cellular senescence and repair of DNA double strand breaks (43,44). E2F3 has been found to be amplified in retinoblastoma patient samples, and its expression has been proposed to inhibit the pro-apoptotic function of the tumor suppressor p53 (23). Amplification of genes encoding the adhesion factor cadherin-11, p130 and MYCN have also been implicated in progression of retinoblastoma (32).

Candidate genes harbored in the region of amplification at 1q32 include those encoding the p53 inhibitors Mdm2 and MdmX. While most human cancers demonstrate mutations in the p53 tumor suppressor gene, which prevents them from undergoing apoptosis before clonal expansion can occur, p53 mutations are notably absent from the majority of retinoblastoma tumors. While the p53 inhibitor MDM2 is over-expressed in some forms of human cancer (45) and is located at the region of amplification observed at chromosome 1q32, mutations in Mdm2 have not been commonly observed in human retinoblastoma (46). Amplification of MdmX, however, has been observed in 65% of retinoblastoma cases. MdmX expression has been found to promote proliferation and to inhibit p53-mediated cell death in retinoblasts lacking *RB1* (47). While MDMX is an attractive target for new therapies to inhibit retinoblastoma, some reports have demonstrated a lack of correlation between the genomic amplification of MDMX and levels of its mRNA expression. Nevertheless, the MDMX inhibitor Nutlin-3 is currently under clinical investigation for the treatment of retinoblastoma, in combination with the p53 inducer, topotecan. This

**FIGURE 140-5** M3 (progression-of-malignancy) events have occurred in these two relatively small tumors, changing the earlier round shape (see Figure 140-4) to one that is more dumbbell-like. The nodular alterations of the initial shapes are postulated to be due to daughter clones of cells that contain a growth-advantage mutation compared to the original tumor cells. This eye would be classified as group B disease because of the larger size of the tumors and their close proximity to the optic nerve (see Table 140-2).

combination was found to produce an 82-fold reduction in tumor burden when injected subconjunctivally in murine models of retinoblastoma, and represents a promising new targeted therapeutic approach for treatment of these intraocular tumors (47).

## 140.5 THE *RB1* CANCER SYNDROME

Patients with heritable and non-heritable forms of retinoblastoma live with very different lifelong cancer risks, due to the presence or absence of the *RB1* mutation in all cells of the body. Patients with a germline *RB1* mutation possess the *RB1* cancer syndrome, putting them at risk of multiple types of tumors, in addition to retinoblastoma. These patients are heterozygous for one inactive or deleted *RB1* allele in every cell type of the body. These inactive *RB1* alleles may be inherited from either parent or may result from endogenous mutations occurring before, at the time of, or after conception. New, postzygotic *RB1* mutations are fairly common events and are the cause of germline mosaicism. If mutational mosaicism is not present, patients have a 45% risk to pass the causative mutation for the cancer predisposition syndrome to each of their children.

The two major consequences of the *RB1* cancer syndrome are the lifelong increase in risk of developing certain cancers, including retinoblastoma, bone, and soft tissue sarcomas, and the risk of transmitting this cancer predisposition to subsequent generations. Because of advances in the

diagnosis and treatment of retinoblastoma, most patients with the *RB1* cancer syndrome no longer die of their eye disease. Rather, premature deaths amongst patients with this syndrome occur from non-ocular cancers. Rapid progress in future, rapid progress in whole genome sequencing, epigenetics and proteomics may provide clinicians with tools for early identification of non-ocular cancers in an effort to reduce the mortality in this group of patients (48).

In more developed countries, patients with the *RB1* cancer syndrome are diagnosed at a relatively early age, usually around 12 months. It is important to refrain from using age at diagnosis to predict genotype. Early diagnosis does not necessarily equate with a germline M1 mutation or the presence of independently arising, bilateral, multifocal tumors (see Figures 140-2, 140-4 and 140-5). The observation of multifocal tumors is extremely helpful in interpreting the genotype of patients since multifocality is associated with the heritable form of disease. The example, shown in Figure 140-4, represents early findings observed during an eye examination of a newly born offspring of one affected parent.

Distinguishing between unifocal and multifocal origin of retinoblastoma is extremely difficult in patients with advanced intraocular disease (Figure 140-6; see also Figure 140-1). In fact, it may be impossible for the geneticist to use information from the ophthalmologist's description of the retinoblastoma to inform genetic counseling or risk assessment. As tumors enlarge, the normal loss of cellular adherence leads to shedding of small clumps of cells into the vitreous (Figure 140-7). In either the heritable or the non-heritable form of the disease, tumor cells can be 'seeded' from the primary tumor into the vitreous or subretinal space prior to treatment (Figure 140-8). Each tumor clump may be the origin of a suspected 'new' tumor. In most cases of advanced disease, the 'new' focus actually represents tumor dissemination from the primary site and not a newly arising tumor focus (see Figure 140-8).

All retinoblastoma patients should be assumed to have a germline mutation until *RB1* genetic testing clarifies the genotype. Since grave consequences follow the failure to suspect or diagnose the presence of the *RB1* cancer syndrome, all newly diagnosed patients should be followed as if they have the heritable cancer syndrome. Most major retinoblastoma centers use examination under anesthesia (EUA) to monitor the retinas for evidence of newly arising retinoblastomas every four to six weeks until either the *RB1* status is clarified or the child reaches five years of age.

### 140.5.1 Retinal Tumors

Ninety-five percent of *RB1* cancer syndrome patients develop retinoblastoma in at least one eye. While the ocular tumors in the *RB1* cancer syndrome are usually bilateral and multifocal, roughly 15% of patients have tumors only in one eye (see Figure 140-3). In about 5% of patients with the *RB1* cancer syndrome, neither eye develops retinoblastoma. Since the transformation of the predisposed

**FIGURE 140-6** Advanced intraocular disease virtually fills the eye in this image. At this stage, multifocal disease cannot be clinically distinguished from unifocal disease. Any independently arising tumor foci have grown into one large tumor mass. (See also Figure 140-1).

**FIGURE 140-7** Vitreous seeding of retinoblastoma in this image is seen as white avascular 'spherules' of tumor suspended in the gel-like vitreous behind the lens. The presence of vitreous seeding places this eye into a more advanced disease group because the cells in these seeds are difficult to destroy during the treatment process.

retinoblast requires a second spontaneous inactivating event at the *RB1* locus, it can be presumed that the remaining 5% who do not develop retinoblastoma never have a cell in either eye that acquires the chance mitotic inactivating event (M2) at the normal *RB1* allele. The age at diagnosis of isolated unilateral retinoblastoma does not identify those patients with the *RB1* cancer syndrome (49).

Notis and colleagues examined the clinical features of *RB1* cancer syndrome patients whose affected parent had unilateral retinoblastoma (50). Among 54 patients with retinoblastoma whose parent had unilateral disease, 91% developed bilateral retinoblastoma with a mean age at diagnosis of 10.5 months. These characteristics do not

**FIGURE 140-8** Digital image of a detached retina shows tumor seeding both in front of the retina (in the vitreous on the left of the image) and attached to the underside of the retina (the retinal vessels can be seen passing over the tumor plaques without distortion on the right side of the image). All of these tumor foci arose from clumps of tumor cells shed from the primary tumor(s) and are not newly arising retinoblastoma from M2 genetic events. Having more than 10 M2 mutations in a single eye is very rare.

differ from the expected ocular features in the whole group of *RB1* cancer syndrome patients.

When retinoblastoma affects both eyes or there is a positive family history of this disease, the patient demonstrates a heritable form. Unfortunately, unequivocal clinical features that are diagnostic of the *RB1* cancer syndrome (primarily bilateral retinoblastoma) are present in fewer than 40% of all retinoblastoma cases. The other 60% of patients with retinoblastoma present unilaterally and the genetics of the disease cannot be clinically deduced. Routine histological examination of the tumors in retinoblastoma patients provides little information about the genetic subgroup to which they belong. In order to detect the 15% of unilaterally affected patients who have the germline mutation and have the *RB1* cancer syndrome, genetic investigation is critical, as described later in this chapter.<sup>2</sup>

<sup>2</sup>The imprecise use of words such as bilateral and hereditary to refer to the group of patients with the *RB1* cancer syndrome contributes to ‘concept clutter’. If bilateral is chosen to describe this group of patients, then 15% of unilateral cases with the *RB1* mutation will be omitted. The word hereditary is an adjective that can be used to describe a disease. However, when referring to the biology of a characteristic capable of being transmitted from parent to offspring, the term heritable is more precise and appropriate. While most *RB1* cancer syndrome patients have bilateral retinoblastoma and may have inherited the predisposing mutation (M1) from a parent, neither of those features is a requirement for patients with the *RB1* cancer syndrome.

## 140.5.2 Non-Ocular Cancers

All patients with the *RB1* cancer syndrome, regardless of whether or not they developed retinoblastoma or were treated for this tumor, are at increased risk of succumbing to a non-ocular neoplasm (Table 140-1). A meta-analysis of 243 non-ocular tumors in retinoblastoma survivors found the following tumor types and relative frequencies: osteosarcoma, 37%; cutaneous melanoma, 7.4%; soft tissue sarcomas, 6.9%; brain tumors, 4.5%; fibrosarcoma, 3.3%; chondrosarcoma, 3.3%; and other sarcoma, 3.3% (51).

Although the terms non-ocular tumors and second malignant neoplasms (SMNs) are commonly used interchangeably, all non-ocular tumors in *RB1* cancer syndrome patients are not necessarily second primary malignancies. They may simply be the first malignancy to occur in a cancer predisposition syndrome patient who, by chance alone, did not develop retinoblastoma. The phrase ‘second malignant neoplasm’ is commonly used by pediatric oncologists and ocular oncologists, who are introduced to their patients by virtue of the patients having a ‘first’ malignant neoplasm, primarily retinoblastoma. Geneticists, on the other hand, deal primarily with family members of an affected patient or child, most of whom do not have a ‘first’ malignant neoplasm, but may be at some risk of the *RB1* cancer syndrome.

There is evidence that aggressive treatment of non-ocular cancer in *RB1* cancer syndrome patients is improving their survival (52). The long-term implications of this finding, however, remain unclear. Abramson and colleagues have documented that, if a patient survives the first non-ocular cancer, a second is subsequently diagnosed, and then a third, fourth and fifth until the patient eventually dies of a non-ocular cancer (53).

There are at least two major factors that contribute to the increased risk of non-ocular cancers in patients with the *RB1* cancer syndrome: (i) the presence of the germline *RB1* mutation and (ii) the type and intensity of retinoblastoma treatment utilized, especially external beam radiotherapy (EBR) (9,54–56). In very young patients, EBR has been noted to cause midface hypoplasia and to increase the risk of developing osteosarcomas, soft tissue sarcomas, and brain tumors. Etoposide, part of the three-drug chemotherapy regimen for retinoblastoma, may also be associated with the development of secondary leukemias (57).

**140.5.2.1 Impact of the Germline *Rb1* Mutation.** The *RB1* germline mutation alone confers an overall risk of development of non-ocular tumors of 6.9 (95% confidence interval [CI], 4.1–11) over what would be expected in the general population (55) (see Table 140-1). This standardized incident ratio (SIR<sup>3</sup>) for the *RB1*

<sup>3</sup>The SIR, or standardized incidence ratio, is the number calculated by dividing the number of observed cases (non-ocular tumors) by the number of non-ocular tumors expected in the general population. The larger the SIR, the greater the effect of the factor being measured.

**TABLE 140-1** Risks of Non-ocular Cancers in 1-Year Survivors of Heritable Retinoblastoma. Radiation ( $n = 849$ ; Person-yr at Risk, 21,706), No Radiation ( $n = 114$ ; Person-yr at Risk, 3602)

Adapted from Kleinerman, R. A.; Tucker, M. A.; Tarone, R. E., et al. Risk of New Cancers After Radiotherapy in Long-term Survivors of Retinoblastoma: An Extended Follow-up. *J. Clin. Oncol.* 2005, 23, 2272–2279.

germline mutation alone was calculated for all sites in 114 patients (3602 person-years at risk) with heritable retinoblastoma who were not treated with radiation. The most common sites of the non-ocular cancers among these 114 patients were bone (SIR 69), soft tissue (SIR 23), uterus (SIR 20), skin (cutaneous melanoma) (SIR 15), and lung (SIR 14).

A study from Great Britain suggests that the presence of the germline *RB1* mutation also increases the risk of smoking-associated cancers, including lung and bladder carcinoma, in older survivors of heritable retinoblastoma who were never treated with radiation (58). Among the 144 patients in this report, 58 developed subsequent cancers. Only 8 of the 58 cancers were sarcomas of bone or soft tissue origin, in marked contrast to the excess of sarcomas reported in the American literature. When compared to the general population, these middle-aged patients had a higher mortality from lung cancer, bladder cancer, and all other epithelial cancers combined. The authors concluded that survivors of heritable retinoblastoma who were not exposed to radiotherapy have a higher lifetime risk of developing late-onset epithelial cancer. They suggested that limiting exposure to tobacco, radiotherapy, and ultraviolet light might lessen that risk (58).

**140.5.2.2 Impact of Radiation Therapy.** The effect of adding the risk caused by radiation therapy to the risk of non-ocular cancer from the germline *RB1* mutation was elucidated (55) in a cohort of almost 1600 patients reported by Eng and colleagues, all of whom received

relatively high doses of radiation in the 1980s (54). The addition of radiation at all doses increased the overall risk of non-ocular cancer in those patients by a factor of 3.1, from 6.9 (95% CI, 4.1–11) to 22 (95% CI, 19–24) (see Table 140-1). In the 1506 New York patients in this series, radiation given before one year of age seemed responsible for the increased risk (59). Since current forms of radiation differ significantly from that applied in the 1980s, the data from the study must be interpreted cautiously and cannot be easily applied to radiation regimens used today. The same risks reported in these studies may not apply to newer approaches to radiation therapy, which involve reduced dosing and better treatment planning for patients.

Despite differences in radiation, the study does demonstrate an association between radiation and non-ocular tumor risk in patients with heritable retinoblastoma. The excess absolute risk per 10,000 person-years conferred by the germline *RB1* mutation alone is 45.1 versus 105.9 when radiation was used in the treatment of retinoblastoma in the *RB1* syndrome patient (55). The most common primary non-ocular neoplasm in *RB1* cancer syndrome patients is osteosarcoma, mostly of the head and neck, with a peak incidence during the growth years of 8–14, irrespective of whether or not radiation was received. Other relatively common non-ocular cancers include soft tissue sarcomas. Cutaneous malignant melanomas may appear during the teenage and early adult years, while midline brain primitive neuroectodermal tumors (PNETs) may occur from birth through age

3 years (Figure 140-9). Less common tumors that occur in the irradiated field include fibrous histiocytoma, leiomyosarcoma, angiosarcoma, rhabdomyosarcoma, meningioma, sinonasal small cell neoplasm, myoepithelioma, and schwannoma. Less common tumors that tend to occur outside the irradiated field include cutaneous malignant melanoma, renal cell carcinoma, Ewing sarcoma, carcinoma of the tongue, and medulloblastoma. Deletion of the chromosomal region 13q14 or mutations in *RB1* are common findings in some of these tumors (e.g. malignant fibrous histiocytomas (20)), even when they are found in patients without a history of retinoblastoma, suggesting that the development of some of these tumors may be more related to loss of *RB1* rather than to radiation exposure as treatment for retinoblastoma.

**140.5.2.3 Impact of Systemic Chemotherapy.** A less common type of second malignancy that occurs following the treatment of childhood cancers, including retinoblastoma, is alkylating agent- and topoisomerase II inhibitor-related acute myeloid leukemia and myelodysplastic syndrome (60). This relatively rare SMN in heritable retinoblastoma patients may be due to the presence of etoposide in the usual triple-drug treatment regimen (carboplatin, etoposide, and vincristine) that was first introduced about 20 years ago (57). Patients who have been found to have developed the topoisomerase II inhibitor-associated acute myelocytic leukemia have most commonly received 9 or 12 cycles of this three-drug regimen. In contrast to radiation, however, systemic chemotherapy is not known to increase the risk for tumors to which the *RB1* cancer syndrome patient is genetically predisposed. Because systemic chemoreduction with local therapy has been in use for only 20 years, the data on second tumor risk is only now being collected.

Due to the potential for increased tumorigenesis resulting from systemic chemotherapy, the use of intra-arterial chemotherapy is currently under investigation for treatment of intra-ocular retinoblastoma. Initially introduced by the Kaneko 20 years ago, Abramson and colleagues have recently reintroduced the use of melphalan when injected directly into the ophthalmic artery using interventional radiological techniques. Recently published results from this group describe 289 successful intra-arterial injections, with a median of three injections per eye, conferring a total event-free two-year survival rate of 70 percent (confidence interval 57.9–82.2%) (61). The long-term results regarding the efficacy of isolated intra-arterial chemotherapy, however, remain to be determined. Potential hazards include the inability to access subretinal tumor seeds that retain the potential for subsequent clonal expansion, as well as fibrosis of the ophthalmic artery, vascular spasms, and stroke. Debate is currently ongoing regarding the recommended use of intra-arterial chemotherapy and its efficacy when used in isolation versus as an adjunct to radiotherapy,

**FIGURE 140-9** This MRI scan shows a midline PNET in an *RB1* cancer syndrome patient who, by chance, had unilateral retinoblastoma. The ocular tumor can be seen as a white mass located nasally in the right eye which is the eye on the left in this image. PNET is a non-ocular neoplasm that is almost always diagnosed before age three years.

chemotherapy and/or enucleation. The very specific delivery of chemotherapy into the eye may also fail to treat patients with high-risk histopathological features for metastatic disease. These features, such as involvement of the optic nerve beyond the lamina cribrosa or choroidal invasion, may predispose children to the development of retinoblastoma at other sites and would be best treated with systemic chemotherapy or enucleation. Intra-arterial chemotherapy may not treat these high-risk features and may put children at higher risk of mortality from local disease extension.

**140.5.2.4 Lipomas in Patients with the *RB1* Cancer Syndrome.** There is some evidence that the presence of lipomas in *RB1* cancer syndrome patients might be associated with an increased probability of developing non-ocular malignancies (62). The observation of 13q14 deletions in lipomas had been reported before 1989, when Sreekantaiah and colleagues described three lipomas and summarized three from the previous literature with deletion of 13q14 (63). Rieder and associates also described loss of heterozygosity of *RB1* in lipomas from a retinoblastoma patient (64). Other groups have observed amplification of *Mdm2* in lipomas, malignant fibrous histiocytomas, and liposarcomas (65). In 2001, a report from Lohmann and colleagues described multiple lipomas linked to an *RB1* mutation in a large pedigree

with low-penetrance retinoblastoma (66). In 2003, that same laboratory reported that deletion of 13q14 distal to the *RB1* locus was present in a high percentage of lipomas (67). Interestingly, in that report, other regions of 13q were recurrently affected in lipomas, including regions near the *BRCA2* and *HMGIC* loci. As an interesting corollary, the related gene *BRCA1* is a transcriptional target of E2F4 and E2F5 transcriptional repressors, and E2F5 has been found to be amplified in some breast cancers.

**140.5.2.5 Trilateral Retinoblastoma.** The term trilateral retinoblastoma is used to describe patients with heritable retinoblastoma and midline brain tumors (see Figure 140-9) (68–72). The designation resonated in part because the pineal gland and pinealoblastoma morphology closely resemble the retina and retinoblastoma. In fact, these patients are *RB1* cancer syndrome patients who develop a second non-ocular neoplasm within the same time frame (0–3 years) as the diagnosis of their eye tumor(s). These midline brain tumors are primitive neuroectodermal tumors (PNETs) of uncertain origin. Patients with the *RB1* cancer syndrome who develop brain PNETs should be considered as having a second non-ocular tumor for both diagnostic and management purposes.

Kivela published a comprehensive meta-analysis of 106 children with trilateral retinoblastoma (69). The median age at diagnosis was five months, with a range from 0–29 months. The diagnosis of trilateral retinoblastoma was most commonly made in the second or third generation of affected patients. The mean time from the diagnosis of retinoblastoma to detection of the PNET was 21 months. Tumors in the region of the pineal gland (77%) were more common than suprasellar tumors (23%), but suprasellar tumors were diagnosed at a significantly earlier mean age (6.5 months vs. 32 months;  $P < 0.0001$ ). The tumors were detected earlier if neuroimaging was routine, but the age of death was the same. No child survived if the tumor was detected without screening, or if the tumor was larger than 15 mm in size at diagnosis. Cumulative 5-year survival was 27% if screening was done. These data suggest that routine magnetic resonance imaging (MRI) with early detection and aggressive treatment of small intracranial tumors might be associated with a better outcome. In our center, we order an MRI with 1-mm cuts, gadolinium enhancement, and fat suppression at diagnosis and every six months until four years of age.

### 140.5.3 Mosaicism of the Germline M1

The concept that new germline *RB1* mutations occur either in the gamete immediately prior to fertilization or in the fertilized egg has been overturned by the documentation of mosaicism in some new cases of heritable retinoblastoma (73–76). In fact, mosaicism

for the ‘founder’ *RB1* mutation is so common in sporadic bilateral retinoblastoma cases that, if the *RB1* mutation is being sought in a family with two affected generations, the search should be initiated in the second-generation individual to avoid confounding the result with mosaicism.

### 140.5.4 Chromosome 13 Deletion Syndrome

In 10–14 percent of *RB1* cancer syndrome patients presenting with clinical dysmorphism and neurologic impairment, chromosome 13 may be entirely absent through deletion. There appears to be an unexpectedly large number of patients with unilateral retinoblastoma in the chromosome 13 deletion subgroup of *RB1* cancer syndrome patients (28,77). It has been postulated that if a large deletion is the first genetic event and subsequent loss of the normal chromosome 13 occurs through non-disjunction, the most common spontaneous mitotic occurrence, the resulting cell would be nonviable. The result might be that fewer tumors arise in these patients, resulting in patients with only unilateral retinoblastoma. This topic is discussed further under the heading Genetic Counseling, later in the chapter.

### 140.5.5 Retinoma (Retinocytoma)

Retinoma (78) or retinocytoma (79) is a benign variant of intraocular retinoblastoma but bears the same genetic implications. Non-ocular cancer has been reported in patients in whom the only previous evidence of the *RB1* cancer syndrome was a retinoma (80,81). The clinical significance of the retinoma is that its presence in one or both eyes of the parent of a child with retinoblastoma may indicate that the parent carries the germline signature of the *RB1* cancer syndrome. This makes an ophthalmologic examination of the parents of a newly diagnosed retinoblastoma patient an important factor in the family history, which can influence genetic counseling.

If a retinoma is observed within the first few years of a child’s life, it may closely resemble type II regressed retinoblastoma lesions (grayish white lesions without prominent capillary vascularity or surrounding retinal pigment epithelial changes, but often containing cavitary spaces) (82). A retinoma is suspected when there is no significant reduction in tumor size following either systemic chemoreduction with local therapy or external beam radiotherapy (Figure 140-10). Retinomas tend to undergo regression and develop surrounding pigment epithelial changes throughout their natural history. Homogeneous gray masses are frequently centered in the region of pigment disruption (83) as described by Gallie and colleagues (78). These lesions are often stable over a long period of time (84,85).

**FIGURE 140-10** A large retinoma filling over half the intraocular volume. Obvious cavitory spaces and calcium deposits are present. The white flecks suspended in the vitreous are commonly described in eyes containing retinomas or retinocytomas.

However, retinomas pose a long-term risk to the patient, because they may undergo malignant transformation to retinoblastoma. The transformation of a retinoma may be the etiology of the rare and unusual finding of active intraocular retinoblastoma in a teenager or adult. Malignant transformation has been described in a 24-year-old woman (83) and a seven-year-old girl (86). The latter had a documented retinoma at age four years, but later developed retinoblastoma with vitreous seeding and eventually underwent enucleation. Singh suggests that this transformation event occurs in only about 4% of retinomas (84). In many centers, focal treatment is used to ablate the lesion in an effort to prevent malignant transformation.

## 140.6 NON-HERITABLE (SOMATIC OR POSTZYGOTIC) RETINOBLASTOMA

Worldwide, non-heritable retinoblastoma accounts for 70–80% of all cases of retinoblastoma. Non-heritable retinoblastoma was initially recognized to have a higher incidence in less-affluent populations more than a decade ago (87). This finding suggested an association with substandard living conditions. Unilateral, nonfamilial cases comprise almost 80% of total cases in less developed countries (30). In contrast, the percentage of unilateral cases in countries of the developed world is consistently reported at about 60%.

Patients who do not have a germline *RB1* mutation develop retinoblastoma only as a result of two rare events in a somatic cell that inactivate both alleles of the *RB1* gene. In this subgroup of the retinoblastoma population, there is no heritable predisposition to cancer, no shortened lifespan, and no risk to pass a genetic cancer predisposition on to subsequent generations.

### 140.6.1 Etiology

The emerging consensus is that environmental factors play a major role in the etiology of non-heritable retinoblastoma. Specific factors that are currently being explored include extreme poverty and poverty-associated dietary deficiencies during pregnancy. Another environmental factor with a possible etiologic role is human papillomavirus (HPV) infection during pregnancy.

**140.6.1.1 Poverty.** Evidence to support the contribution of poverty to the observed geographic excess of non-heritable retinoblastoma can be found in economically depressed, less developed countries. In North America, retinoblastoma occupies sixth place on the list of most common solid childhood cancers. However, the order of the list is markedly different in the tropical African country of Nigeria (88), where poverty and malaria are widespread and unilateral retinoblastoma is common. Retinoblastoma would top the list, if it were not for the slightly higher incidence of malaria-associated Burkitt lymphoma (88).

Namibia is an impoverished country on the arid southwest coast of Africa, where, in contrast to Nigeria, malaria is not a public health problem. The incidence of malaria-associated Burkitt lymphoma is very low; however, the prevalence of retinoblastoma is as high in Namibia as in Nigeria (8). The prevalence calculations in the Namibia study (5.8 cases per million children younger than 15 years) can be adjusted to approximately 19 cases per million children under 5 years of age and are nearly double those reported from Sweden and Singapore (11 cases per million children under 5 years of age).

Recent data from Orejula and colleagues suggest that the specific factor that is common among populations that live in poverty and may contribute to the increased number of patients with retinoblastoma is a deficiency of fruits and vegetables in the diet of pregnant mothers. Data from an isolated population in Mexico suggest that such a deficiency may increase the likelihood of having a child with the non-heritable form of retinoblastoma (89). In light of this new information, it is of more than passing interest that Alaskan natives, a population in which pregnant mothers have limited access to fresh fruits and vegetables for extended periods, likewise show an unexpectedly high incidence of retinoblastoma (90). The non-heritable form of the disease may be more common in situations in which maternal intake of folate and vitamins during pregnancy are inadequate. This association of folate deficiency and increased risk of retinoblastoma is discussed later in the chapter, in the section on prenatal assessment and diagnosis. Poverty also contributes to poor outcomes because of delayed access to treatment. A direct correlation between advanced retinoblastoma at diagnosis and poverty has been reported in Mexico (91).

**140.6.1.2 Human Papillomavirus.** HPV inactivation of pRb is the major cause of human cervical cancer. At least two groups have detected HPV DNA sequences in

retinoblastoma tumor tissue (92,93). The role of HPV-associated post-translational inactivation of pRB in the etiology of non-heritable human retinoblastoma is still unknown, but is under active investigation.

### 140.6.2 Diagnosis

The absolute diagnosis of non-heritable retinoblastoma cannot be achieved even with *RB1* mutation analysis, since it involves proving the absence of a mutation in any cell outside of the tumor focus. The residual risk after a laboratory has been unable to find an *RB1* mutation from a peripheral blood sample depends on that laboratory's mutation detection accuracy. Some laboratories can reduce the risk that sporadic unilaterally affected patients have the *RB1* cancer syndrome from about 15% to between 1% and 2% if they find no mutation in a blood sample. Other labs with a higher failure of detection rate will not accept blood only from patients with sporadic unilateral retinoblastoma. As a CLIA laboratory funded by the National Eye Institute, our laboratory has developed no cost, high-throughput techniques for whole gene exon sequencing and detection of chromosomal abnormalities through multiplex ligation-dependent probe amplification. These techniques allow the detection of point mutations, small and large insertions or deletions, truncations, inversions, and transpositions with greater than 95 percent sensitivity and specificity, returning results to the requesting clinician within one week.

Most patients with unilateral sporadic retinoblastoma present with advanced intraocular disease because vision is not affected in the other eye (see Figures 140-1, 140-3 and 140-6). In these cases, the eye is filled with tumor, preventing any determination of whether the tumor was originally unifocal or multifocal in origin. *RB1* analysis in these patients reveals that more than 10% will have an *RB1* gene mutation (94) and as many as 15% may have constitutional microdeletions of chromosome 13q14.

## 140.7 FEATURES OF RETINOBLASTOMA COMMON TO HERITABLE AND NON-HERITABLE CASES

### 140.7.1 Clinical Features and Age at Diagnosis

Retinoblastoma can be found at birth (20) or can be initially diagnosed as late as age five to seven years. Neonatal diagnosis has also been described. Classically, however, most cases are brought to medical attention before the age of three. Once the retina is terminally differentiated, the risk of newly arising retinal tumors has passed. Common presenting signs of retinoblastoma in the developed world include leukocoria (white pupil) (Figure 140-11) and strabismus (misalignment of the eyes). If the fovea (that part of the retina responsible for fine central vision) is replaced

**FIGURE 140-11** Leukocoria is present in the left eye of this child. It is obvious in this flash photograph taken in a dimly lit kitchen when the child's pupils are naturally dilated. The light from the flash attachment on the camera is reflected by the white retinoblastoma in the left eye. This is the classical asymmetrical 'abnormal red reflex', sometimes referred to as 'cat's eye', 'animal eye', 'gleam', 'glow', 'glimmer', or 'something is not right with my baby's eye'. In bright ambient light, this child's pupil would be small and the leukocoria would not be seen. This is often the case in the pediatrician's office. This is also the reason that the parents or other family members see this sign before the pediatrician in over 85% of cases.

by the tumor in one eye, strabismus due to the loss of central vision in that eye may occur. Even total lack of vision in one eye of a child may go unrecognized by family members. Unilateral visual loss will not cause signs of vision impairment because of the normal vision in the fellow eye.

The tumor does not cause pain or discomfort as it enlarges and virtually never causes a red or inflamed eye except late in the course of the intraocular disease (see Figure 140-3). In very advanced intraocular disease, the tumor mass can interfere with the normal intraocular fluid outflow and result in glaucoma, redness, and pain. Proptosis (bulging of the eye from the orbit, usually due to the expansion of a tumor mass in the orbit) is a rare presenting sign of retinoblastoma in developed countries, but in a 2002 report, proptosis was the second most common presenting sign in Congolese patients (95). Extraocular disease at initial diagnosis is also common in Central and South America (30). In developed countries where there is relatively easy access to medical care, metastatic disease develops in fewer than 5% of patients with retinoblastoma. It is so rare at diagnosis that spinal tap and bone marrow aspiration/biopsy are no longer performed routinely unless there is other evidence of tumor outside the eye.

In the absence of a known family history of the disease, the early months of retinoblastoma growth in a child's eye usually go undetected by both family members and primary care physicians. Even if the pediatrician or family practitioner performs a red reflex test (Figure 140-12) or examines the optic nerve with a direct ophthalmoscope in the first year of the child's life, he or she may miss the tumor and not suspect its presence, unless it is large enough or located in a part of the retina where it will reflect the light entering the pupil.

Retinoblastoma shows no gender predisposition. The tumor occurs with equal incidence in right and left eyes, and is present in both eyes in about 20–40% of all

**FIGURE 140-12** This was one of two presumed retinomas in this child's eye. It did not respond at all to treatment with systemic chemotherapy but was successfully eradicated with repeated applications of transpupillary 532-nm laser energy. These presumed early retinomas have not yet developed the classical retinal pigment epithelial changes initially described for these lesions. It is very difficult to make the diagnosis prior to treatment. This lesion is grayer than might be expected, but the color separation from retinoblastoma is not reliable.

cases, depending on what region of the world is being sampled. In the United States, nearly 90% of diagnoses are made before the patient is five years old (96). Of 400 consecutive patients, only 34 (8.5%) were five years of age or older at the time of diagnosis, and 26 of these had active tumor (the remaining eight had retinoma or retinocytoma) (97). All 26 children had sporadic, unilateral disease; their average age was six years. A small number of older children and adolescents, and two adults, have been reported as having active retinoblastoma, most likely arising from a previous retinoma (see previous section on retinoma).

### 140.7.2 Survival

In bilateral patients, relatively small tumors often cause visual symptoms and lead to early detection and treatment. The overall survival of retinoblastoma exceeds 95% in developed countries. In contrast, survival of ocular tumors may be as low as 50% in some Latin American and African countries because of limited access to medical care (30). Unfortunately, early detection does not always equate with better treatment outcome. Advanced intraocular retinoblastoma has been diagnosed by prenatal ultrasound imaging at 21 weeks' gestation (98), documenting a very early inception and rapid growth prenatally. When retinoblastoma was diagnosed and the extent of disease evaluated in three-month-old patients, almost one third of patients had advanced disease (99).

In a recent Mexican study, there was a direct correlation between advanced retinoblastoma at diagnosis, reduced survival and poverty (91).

### 140.7.3 Natural History of Retinoblastoma in the Patient

Patients with the *RB1* cancer syndrome and those with the non-heritable, somatic form of the disease cannot always be distinguished on the basis of tumor morphology, growth rate, or extent of disease. If undiagnosed, retinoblastoma expands locally by filling the eye (see Figure 140-1) and extending into the optic nerve, orbit, and brain. Blood-borne distant metastases appear most commonly in bone marrow, bone, and brain. The development of metastases is most commonly associated with the length of time that active retinoblastoma is present in an eye (see Section 140.7.2). The profiles of patients at high risk of metastatic retinoblastoma fall into two broad groups. The first is the older child, age three to five years, who presents with advanced unilateral intraocular retinoblastoma and has had clinically apparent symptoms for months to years without diagnosis or treatment. The second group is characterized by the child with bilateral retinoblastoma in whom multiple intraocular recurrences have been treated without success over several years in attempts to salvage vision in an only eye. Parents who are reluctant to agree to enucleation of a second eye may be increasing their child's chance of the development of metastatic disease.

### 140.7.4 Natural History of Retinoblastoma in the Eye

Early intraretinal intraocular tumors are composed of cells which are identical daughter cells of the 'founder' retinoblast. Because all of the cells that make up early small tumors are identical, they have a common growth rate and expansion of the lesion is symmetrical (see Figures 140-2 and 140-4). As chromosomal aneuploidy gradually develops, daughter clones of tumor cells with a growth advantage develop (Figure 140-13; see also Figure 140-5). Irregular and nodular tumor growths (see Figure 140-13) are the clinical manifestation of progression-of-malignancy changes (M3) and almost always involve the largest tumors first.

In addition to being composed of identical tumor cells, early retinal tumors share two other characteristics: (i) the tumor cells are adherent to each other, and (ii) a blood supply is required for growth beyond a relatively small size. Anchorage independence eventually develops as this malignancy progresses. The clinical corollary of achieving anchorage independence is the breakup of tumor into small clumps of cells that seed the vitreous or subretinal space (Figure 140-14). The clinical observation that seeding takes place from a specific region of the growing tumor, most often an area that has shown rapid growth, suggests that this is a clonal process involving additional genetic alterations.

**FIGURE 140-13** This large tumor shows two sites where growth advantage mutations may account for rapid focal expansion of the tumor. Additional M3 events have occurred, bestowing likely gain-of-anchorage-independence mutations. The tumor cells from the new clone at site 1, indicated by the arrow, are about to be shed into the vitreous as local vitreous seeding. At site 2, the cells are beginning to spread beneath the retina into the subretinal space. This eye would be classified as having group C disease because of the localized seeding.

**FIGURE 140-14** This small tumor has a 'nipple' on the tip from which tumor cells will be shed into the vitreous as a presumed result of acquired anchorage independence M3 mutations. This would be classified as a group C eye because of the local vitreous seeding.

Once vitreous seeding has occurred, the free-floating clumps of tumor cells expand without an intrinsic blood supply (Figure 140-15). Advanced intraocular retinoblastoma is characterized by these very large avascular masses within both the vitreous and the subretinal space. Invasion into the optic nerve and into the choroid may subsequently develop and increase the risk of metastatic disease.

**FIGURE 140-15** Vitreous tumor seeds have spread diffusely into the vitreous. At this stage, salvage of the eye is questionable. The fine vitreous seeding is sequestered from systemically administered chemotherapy and may begin to grow when the chemotherapy is discontinued. Some have already settled on the retinal surface, where they will establish new tumor foci.

### 140.7.5 Classification of Retinoblastoma

Classification systems vary significantly from cancer to cancer. In general, staging systems look at the patient as a whole and attempt to assess the extent of disease involvement in the patient and to determine the likelihood of patient survival. Grouping systems evaluate the involvement of the organ of origin in an effort to assess the best treatment strategy for the organ's survival. 'Staging' uses the entire medical record as a source of information. In contrast, 'grouping' in retinoblastoma management is based on the findings in the eye, usually determined during an examination under anesthesia (EUA) of the eye.

Most patients with childhood solid tumors other than retinoblastoma are staged based on the extent of disease in the patient following evaluation of an incisional or excisional biopsy. Retinoblastoma is unique among the solid childhood tumors, in that a tissue diagnosis has never been a requirement before treatment initiation. Since retinoblastoma is frequently confined to the eye, biopsy is contraindicated and results in upstaging of the patient.

The Reese-Ellsworth grouping system (Table 140-2), which focuses on the likelihood of salvaging the eye, has been used since the early days of megavoltage radiation in the 1960s (100). In 2005, there was international collaboration to update the classification of eyes with retinoblastoma. A new grouping system based on the natural history of the intraocular disease rather than response to a specific treatment modality was proposed to replace the Reese-Ellsworth system (Table 140-3) (37). Chantada and colleagues presented a staging system similar to those that currently exist for other solid childhood malignancies as a tool to assist pediatric oncologists in

**TABLE 140-2** Reese-Ellsworth Group Classification of Eyes with Intraocular Retinoblastoma

Group I – Very Favorable	
Ia	Solitary tumor 4 DD at or behind the equator
Ib	Multiple tumors, none 4 DD, all at or behind the equator
Group II – Favorable	
IIa	Solitary tumor, 4–10 DD, all at or behind the equator
IIb	Multiple tumors, 4–10 DD, behind the equator
Group III – Doubtful	
IIIa	Any lesion anterior to the equator
IIIb	Solitary tumors larger than 10 DD behind the equator
Group IV – Unfavorable	
IVa	Multiple tumors, some larger than 10 DD
IVb	Any lesion extending anteriorly to the ora serrata
Group V – Very Unfavorable	
Va	Massive tumors involving over half the retina
Vb	Vitreous seeding

DD, disk diameter.

From Reese, A.; Ellsworth, R. The Evaluation and Current Concept of Retinoblastoma Therapy. *Trans. Am. Acad. Ophthalmol. Otolaryngol.* 1963, 67, 164–172.

treating the disease (Table 140-4) (29). The development of the new staging and grouping systems were coordinated so that they could be used together to completely describe the disease in any patient.

Murphree observed that the most significant feature of the intraocular tumor that impacted the likelihood of salvaging the eye was the presence or absence of intraocular tumor seeding (37,101) (compare Figures 140-4 and 140-5 with Figures 140-7 and 140-8). He divided all intraocular disease based on whether seeding had occurred. Eyes that had not developed seeding eventually became groups A (see Figure 140-4) and B (Figure 140-16; see also Figure 140-5) in the new international classification system. Eyes that had previously developed seeding became groups C (see Figure 140-13) and D (see Figures 140-7,140-8 and 140-15). Groups were separated to give ophthalmologists reliable predictors concerning final visual acuity outcomes and to allow consensus enrollment of retinoblastoma patients into multicenter clinical trials. Group A eyes are limited to those eyes containing small tumors (less than 3 mm in greatest diameter) that are also located at a sufficient distance from the fovea and optic nerve that local treatment of these lesions with laser is not likely to cause permanent visual impairment (Figure 140-4). Group B (see

Figures 140-2,140-5,140-12 and 140-16) is assigned to all other eyes with no seeding regardless of the location or size of the tumor.

Group C eyes are separated from group D eyes by the location and extent of the seeding. Group C eyes have minimal localized seeding (see Figures 140-13 and 140-14), whereas group D eyes have massive, diffuse seeding (see Figures 140-7,140-8 and 140-15). Group E includes those eyes that present at diagnosis with such extensive intraocular disease that their function and/or structure have been destroyed.

There is nothing in the classification systems for staging or grouping retinoblastoma that correlates with heritability. This is true whether using the older Reese-Ellsworth system or the newly developed international classification for grouping and staging.

### 140.7.6 Diagnosis and Treatment of Intraocular Retinoblastoma

The treating pediatric ophthalmologist must first assess whether or not the suspected signs present in the child referred because of the possibility of retinoblastoma are sufficiently strong to warrant an EUA. That first assessment is made in the office with a brief retinal exam and an ultrasound examination of the eye. If an intraocular mass that contains calcium is present, then a diagnosis of retinoblastoma is highly likely. A computed tomography scan can then be avoided (because of the unnecessary radiation) and the child can have a high-resolution MRI scan of the orbit and brain with thin sections, gadolinium enhancement, and fat suppression to exclude extraocular extension of disease or a concomitant PNET (see Figure 140-9).

At the staging EUA, a thorough eye exam is performed with assessment of intraocular pressure, a portable slit lamp examination, a retinal exam with scleral depression, and a retinal drawing. Digital images of the retina and ultrasound studies are also obtained. Grouping of each eye is performed according to the new International Group Classification of Retinoblastoma at most centers.

**140.7.6.1 Unilateral Retinoblastoma.** Primary treatment generally consists of primary enucleation (see Figure 140-1) for group E eyes. This is always recommended if the disease is unilateral. In most centers, it is recommended to have primary enucleation in unilateral eyes with very extensive intraocular seeding (group D). Systemic chemoreduction is difficult to justify for a young child when one eye is completely normal and the other has advanced disease (groups D and E).

**140.7.6.2 Bilateral Retinoblastoma.** For eyes in which salvage of some useful visual acuity is likely (bilateral groups A through D), systemic chemoreduction with local consolidation is commonly used. The Children's Oncology Group, a cooperative clinical trials group of the NCI, enrolls patients with Group B

**TABLE 140-3 International Group Classification of Eyes with Intraocular Retinoblastoma**

Group A – Very Low Risk	Discrete retinal tumors, none larger than 3 mm in diameter. All tumors located at least 3 mm from fovea and 1.5 mm from optic nerve. No vitreous or subretinal seeding. No retinal detachment allowed.
Group B – Low Risk	Discrete retinal tumors of any size or location. No vitreous or subretinal seeding. 5-mm-wide cuff of subretinal fluid around base of tumor allowed.
Group C – Moderate Risk	Discrete retinal tumors of any size or location. Any vitreous or subretinal seeding must be local, fine, and limited. Retinal detachment, current or past, 1 quadrant.
Group D – High Risk	Massive and/or diffuse endophytic or exophytic tumors. Massive and/or diffuse vitreous and/or subretinal seeding or masses. Retinal detachment, current or past, 1 quadrant.
Group E – Very High Risk (One or More)	Irreversible secondary glaucoma. Massive intraocular hemorrhage. Aseptic orbital cellulites. Tumor anterior to anterior vitreous face. Tumor touching lens. Diffuse infiltrating retinoblastoma. Phthisis or prephthisis.

From Murphree, A. L. The Case for a New Group Classification of Intraocular Retinoblastoma. *Ophthalmol. Clin. N. Am.* 2005, 18, 41–53.

**TABLE 140-4 International Staging Classification of Patients with Retinoblastoma**

Stage 0	Patients treated conservatively without enucleation Eyes subject to group classification and systemic or local treatment
Stage I	Tumor completely resected by enucleation
Stage II	Microscopic residual tumor following enucleation
Stage III	Regional extension of disease
IIIa	Overt orbital disease
IIIb	Preauricular or cervical lymph node extension
Stage IV	Metastatic disease
IVa	Hematogenous metastasis
IVa1	Single lesion
IVa2	Multiple lesions
IVb	CNS extension
IVb1	CNS mass
IVb2	Leptomeningeal disease

CNS, central nervous system. Data from Chantada and colleagues (2005), Murphree (2005), and Reese and Ellsworth (1963).

through D disease into individual trials. In most eyes, there is a reduction in the volume of the tumor by 50–70% after the first cycle of systemic chemoreduction. We schedule the child for an EUA on day 0 of each cycle and perform focal laser consolidation prior to administering three agent chemotherapy (carboplatin, vincristine and etoposide).

The most commonly used duration of systemic chemotherapy is for six cycles over five to six months. Each cycle consists of administration of chemotherapy in an outpatient hospital setting and then allowing three to four weeks for the bone marrow to recover.

**FIGURE 140-16** In this group B eye, there are five separately arising retinoblastomas ranging from a barely detectable pinhead-sized lesion along the lower left edge of the image to the large central lesion located in the fovea. All are round except where structures such as the optic nerve or other tumor masses have distorted that shape. The posterior pole of the eye, where all these tumors are located, has the highest concentration of retinoblasts.

We treat each retinoblastoma lesion with laser consolidation at every EUA. Inadequate local consolidation can be associated with an increased risk of recurrence of treated lesions. The ideal treatment outcome is a chorioretinal scar that either is flat or contains a mass of calcified tumor debris (regression types 1 and IV). We make every effort to reduce the homogeneous type II regression pattern to a calcified scar with repeated laser application.

### 140.7.7 Cost Issues Associated With Treatment and *Rb1* Testing

The costs associated with treating a child with bilateral group D intraocular disease with systemic chemotherapy and laser consolidation in American pediatric specialty hospitals frequently often exceeds \$200,000. Patients traveling from other countries for treatment and who do not have American insurance are required by some American hospitals to deposit as much as \$150,000 before the hospital will see the child. Costs of this magnitude mean that, in developing countries and in the developed world, governmental health care policy should focus on prevention. Genetic counseling and early diagnosis are the key ingredients in such an effort.

In many developing countries, even those with access to chemotherapy for the treatment of children, parents are sometimes required to purchase the chemotherapeutic drugs and bring them to the hospital. Our current approach to primary treatment may not be a viable alternative for the majority of the world's retinoblastoma cases.

### 140.7.8 Regressed Retinoblastoma

The term regressed retinoblastoma has been misapplied to the lesion more correctly labeled retinoma or retinocytoma. Rarely, spontaneous massive necrosis of a very large intraocular tumor is associated with an aseptic orbital cellulitis and eventual shrinkage and disorganization of a blind eye (phthisis).

## 140.8 CLINICAL GENETICS AND GENETIC COUNSELING

The presence of a germline mutation in *RB1* has far-reaching implications for the retinoblastoma patient and his or her family. The discovery of a heritable mutation in *RB1* can impact the optimal treatment of the tumor, the risk of non-ocular cancer, and long-term survival as well as the occurrence risk of the *RB1* cancer syndrome in offspring and in other family members. Free testing for *RB1* mutations is currently available through eyeGENE, a program funded by the National Eye Institute. The American Society of Clinical Oncologists (ASCO) recommends genetic counseling for families because of the possibility of a heritable predisposition to retinoblastoma and other cancers. It is important to inform at-risk individuals about the availability of testing for constitutional mutations in *RB1* (ASCO policy statement).

### 140.8.1 Genetic Counseling

Genetic counseling is as important for the family of a child with retinoblastoma as it is for the adult survivor of this childhood cancer. Both families with clearly

hereditary disease and those with a single affected individual can benefit from genetic counseling.

When the geneticist participates in the early diagnosis and treatment stages of retinoblastoma, genetic testing and counseling can be facilitated. Because of the possibility of a chromosome 13 deletion, the child with retinoblastoma requires an assessment of his or her developmental progress as well as an examination for dysmorphic features. Parents of a child with retinoblastoma often have subsequent pregnancies that require genetic counseling and prenatal diagnosis.

Counseling the adult survivors of retinoblastoma can be challenging as well. Counseling becomes less straightforward in those circumstances in which DNA testing on a blood sample does not reveal an *RB1* mutation. A non-diagnostic test must be carefully explained to the patient since an undetectable, possibly mosaic mutation could yield an apparently normal result. When the adult retinoblastoma survivor has a blind spouse, the genetics professional should be prepared to address the risks of other hereditary causes of blindness. When both the proband and the spouse are blind, one with retinoblastoma and the other with another heritable cause of visual loss (e.g. retinitis pigmentosa), the counseling and testing process can become quite complex.

The primary issue that is of concern to the adult survivor of heritable retinoblastoma who seeks genetic counseling is the chance of blindness in his or her future affected children. Enucleation of one eye alone does not create significant visual impairment or legal blindness unless there is a tumor affecting the central retina in the fellow eye. In our experience, when newborns at risk of retinoblastoma are followed from birth with dilation of the pupil and scleral depression by an ophthalmologist looking for retinoblastoma, the likelihood of bilateral blindness is less than 10%. This information can be very useful in the setting of genetic counseling and is often reassuring to affected families.

It is also our observation that adult survivors of hereditary retinoblastoma who have not experienced a non-ocular cancer will minimize the risk of those cancers. The geneticist needs to raise this issue as well, so that the family understands the range of risks that any affected patient with the *RB1* cancer syndrome will face.

In order to counsel the family appropriately, the genetic counselor needs to assess the family's risk of a heritable mutation in *RB1*. A detailed three-generation pedigree should include the father's age, miscarriages, infant deaths, infertility, the use of assisted reproductive technology, other relatives with developmental delay or birth defects, and the history of blindness or other cancers and their age of onset in all grandparents and other first- and second-degree relatives.

Medical records and pathology reports of the tumor should be carefully reviewed to determine the nature and extent of the retinoblastoma—bilateral versus unilateral, multifocal versus unifocal. Even when this data

is complete and accurate, it does not provide a certain diagnosis of heritability.

Genetic counseling is particularly helpful when a baby is diagnosed in early infancy. For example, the counseling session may predate the diagnosis of a second focus of retinoblastoma in the same or the other eye. The risk of the development of multifocal disease is highest (16%) for children whose presenting tumor is diagnosed before one year of age, and lower (2.2%) when the diagnosis is made after age one (53,102). The mean time to the diagnosis of a new focus of retinoblastoma is 0.74 years. Therefore, when counseling a family with a child with sporadic unilateral retinoblastoma diagnosed in infancy, the counselor should qualify the risk assessment and encourage a follow-up visit for genetic risk reassessment at age two to three years.

Ophthalmology examinations on all first-degree relatives should be completed prior to genetic counseling. The presence of a retinoma in an asymptomatic parent has immediate implications for the patient and for the family. At the time of diagnosis, the family may be struggling to cope with this devastating news and overwhelmed with difficult treatment choices. Nevertheless, waiting even a few months to complete these exams can mean that another affected child might be conceived before the family is aware of the genetic risks.

Finally, the counselor needs to be aware of the proband's age, general health, and developmental status. Imaging studies of the brain are required to exclude extraocular extension of retinoblastoma or a concomitant PNET. The developmental status of the infant is an important clue to his or her overall well-being. Delayed motor and social milestones do not necessarily signal a problem in blind children. Normal children with visual impairment attain these skills at a later age than sighted children. Delayed speech, however, can represent a significant finding. If there is any concern about neurodevelopmental status, mental retardation, or dysmorphic features, a clinical genetic evaluation should be undertaken. The results of chromosome analysis and fluorescence in situ hybridization (FISH) studies for 13q14 should also be reviewed (26).

Although there is no known parent-of-origin effect in retinoblastoma, new germline mutations in *RB1* preferentially occur on the paternally inherited chromosome 13. Interestingly, patients with germline mosaicism also have more mutations on the paternally derived chromosome 13, suggesting that the high risk of mutation persists in the paternal genome even after fertilization. Advanced paternal age is a known risk factor in retinoblastoma.

## 140.8.2 Cytogenetics

Since 1976, when Franke and Kung proposed a relationship between bilateral retinoblastoma and 13q14 deletion (103), high-resolution cytogenetic analysis has become a

standard part of the evaluation of children with retinoblastoma. Deletions of varying sizes and other rearrangements of chromosome 13q14 are commonly identified. In a group of 203 patients with retinoblastoma, deletions were seen in approximately 5% of unilateral and 7.5% of bilateral retinoblastoma patients (28). As small deletions can be missed with conventional cytogenetic banding, FISH studies for the *RB1* locus are now recommended to augment the cytogenetic evaluation of the child with bilateral or unilateral retinoblastoma. Large numbers of cells should be examined to detect mosaic deletions, which is easily accomplished with FISH studies.

When a deletion is mosaic, which occurs in 1% of cases, the risk of retinoblastoma is not necessarily reduced. Only 7% of patients with 13q14 deletion mosaicism did not develop retinoblastoma in Kivela and colleagues' series (104). In the same report, the diagnosis of retinoblastoma was delayed because a mosaic 13q deletion was erroneously assumed to construe a lower risk of retinoblastoma. A recent study from a major retinoblastoma center in India reported that FISH studies have demonstrated constitutional deletion of chromosome 13q14 in almost 15% of unilateral sporadic retinoblastoma patients (38) without any clinical evidence that they might be *RB1* mutation carriers.

There are several reports of retinoblastoma in children with X; 13 translocations. Interestingly, the breakpoint need not involve 13q14. Even though the breakpoint involves another area on 13q, the intact *RB1* was disabled when inactivation from the X chromosome spread to the adjacent 13q14 region (105).

**140.8.2.1 Chromosome 13q Deletions.** Children with constitutional 13q14 deletions may have a particular recognizable pattern of facial dysmorphism, additional anomalies, and disabilities ranging from severe mental retardation to relatively mild speech delay. Typical facial features (26,106,107) include a broad high forehead, depressed and broad nasal bridge, bulbous nasal tip, anteverted earlobes, and a long prominent philtrum. Difficult intubation due to macroglossia has been reported in children with retinoblastoma due to 13q deletions (108). Although deletions are less common in familial retinoblastoma, we have seen an affected mother with borderline intelligence and a chromosome 13q deletion, whose affected child had similar learning problems.

**140.8.2.2 Retinoblastoma and Congenital Anomalies.** FISH studies should not be limited to children with facial dysmorphism or developmental delay. Some patients with small 13q deletions may have no discernible dysmorphism or developmental delay. Conversely, it is not safe to assume that patients with retinoblastoma who are developmentally delayed must have a chromosome 13 deletion. Aside from genetic counseling for retinoblastoma, some retinoblastoma patients will deserve a complete genetic assessment for other indications. We have several retinoblastoma patients who also have apparently unrelated genetic syndromes; one girl with

sporadic retinoblastoma, developmental delay, and a seizure disorder has fragile X syndrome. In our clinic, there are several retinoblastoma patients with isolated congenital anomalies (clubfoot, dysplastic ear) and others with autism or unexplained mental retardation. As yet, no relationship between retinoblastoma and other anomalies has been established outside of the deletion 13q syndrome.

### 140.8.3 *RB1* Analysis

*RB1* analysis can determine which retinoblastoma patients have heritable disease and can identify those individuals with an increased risk of non-ocular tumors. Functional domains and conserved sequences in *RB1* are hot spots for mutations. Many *RB1* mutations disrupt gene expression, and no functional protein product is produced. Because missense mutations allow formation of an *RB1* protein that may have some functional utility, a milder phenotype with a lower tumor-to-eye ratio and later onset can be seen in affected families. Missense mutations have been reported in several low-penetrance pedigrees.

Although gene sequencing is the mainstay of molecular diagnosis in retinoblastoma, this technique alone will detect only about 70% of mutations. Large deletions and gene rearrangements will not necessarily be detected by gene sequencing alone. Quantitative multiplex polymerase chain reaction (PCR) and MLPA can increase the detection rate 15% or more. Gene sequencing cannot reliably detect mosaicism of less than 20%. Epigenetic changes are also important, since hypermethylation of the promoter region disables *RB1* in approximately 10–11% of tumors from patients with unilateral sporadic disease. When a comprehensive testing protocol is carried out, the detection rate for *RB1* mutations exceeds 95%.

### 140.8.4 Testing Issues

Although it is rarely available, DNA from fresh frozen tumor can be useful in a genetic testing strategy. If a mutation is detectable in the tumor, a negative blood result is more reliable, although, mosaicism cannot be excluded.

**148.8.4.1 Bilateral Retinoblastoma.** When the patient has bilateral retinoblastoma, a mutation in *RB1* is a virtual certainty. DNA testing can be carried out on blood alone because, even if a mutation is not detected, the patient's status is unchanged. All patients with bilateral retinoblastoma are presumed to have a germline mutation, albeit sometimes mosaic or sometimes undetectable.

**140.8.4.2 Sporadic Unilateral Retinoblastoma with Fresh Tumor.** When the proband has sporadic unilateral retinoblastoma, a fresh frozen sample of the tumor tissue as well as a blood sample may be sent for analysis. In unilateral cases, the tumor tissue can be used first to identify both *RB1* mutations before the blood studies are

initiated. If one or both of the mutations cannot be identified in the tumor, then normal studies in the blood will not be useful for genetic counseling purposes, since the mutation may be present but not detectable.

**140.8.4.3 Sporadic Unilateral Retinoblastoma without Fresh Tumor.** When the proband has sporadic unilateral retinoblastoma and a fresh frozen tumor specimen is not available, it may be useful to test blood alone. Abnormal results in blood are definitive, allowing a diagnosis of heritable retinoblastoma. A non-diagnostic test for *RB1* gene mutation does not exclude the possibility of heritable disease. Patients need careful counseling to appreciate that they still have a risk of an undetected *RB1* mutation whenever there are normal results in blood, whether there are results for tumor tissue or not.

**140.8.4.4 Possible Uninformative or Unexpected Results.** Patients should be counseled about the possibility of uninformative results prior to analysis. The higher the detection rate, the less likely it is that patients will have to face the issue of uninformative results, which makes the selection of a testing laboratory of critical importance. Occasionally, completely unexpected results are obtained from *RB1* testing. In one unilateral sporadic patient, a normal unaffected parent was found to share a small 13q14 deletion with the affected child. This information was very difficult for the family to accept. Prior discussion of this possibility with the family before testing could have mitigated their distress.

### 140.8.5 Mosaicism

Mosaicism is common in retinoblastoma, and it is a factor that, because it can never be ruled out completely, must be thoroughly discussed before genetic testing. Mosaicism occurs in at least 10% of individuals with germline mutations in *RB1*, affecting both new unilateral and bilateral cases. Mosaicism should be suspected when a parent has unilateral retinoblastoma and his or her child has bilateral retinoblastoma.

Gene sequencing can miss low-level mosaicism. Mosaicism probably accounts for most of the non-detectable mutations in the blood of individuals with bilateral retinoblastoma. When the mutation can be identified in affected family members in subsequent generations, the founding affected member of the family may be tested with PCR and an allele-specific oligonucleotide probe, a more sensitive technique for the detection of mosaicism. Lohmann's group presented unpublished data at the XII International Retinoblastoma Symposium in 2005 indicating that, of 22 multiplex families in which the transmitting parent had unilateral retinoblastoma, mosaicism was detected in 4 of 22 affected parents.

### 140.8.6 Testing the Parents

When a child has a detectable *RB1* mutation, first-degree relatives should also be tested for the same mutation.

Parents may be unprepared for this step unless it is addressed early in the counseling process. Even with this preparation, it is a turning point that may be difficult for some parents who perceive, for the first time, that they are at risk, not just their children. Familial *RB1* mutations are identified in healthy unaffected parents. This may be most understandable with missense mutations in which the *RB1* gene remains capable of producing a gene product, but it has also been observed with other types of mutations. Some of these parents have no ocular findings. Their non-ocular cancer risk is difficult to assess, since no long-term studies of this group are available.

It must also be recognized that when *RB1* testing results are normal in a parent, germline mosaicism remains a possibility. For this reason, normal results in the parents of an affected child with an *RB1* mutation should be interpreted with caution. Prenatal diagnosis for the *RB1* mutation identified in the proband should still be offered for future pregnancies since germline mosaicism cannot be excluded in the parent.

### 140.8.7 Linkage Analysis

Linkage analysis of retinoblastoma families may be helpful in establishing an at-risk haplotype when direct gene analysis does not reveal the mutation in *RB1*. As an indirect test, linkage analysis is less reliable than direct mutation analysis, and it should never be used as the preferred method of testing. At first glance, linkage analysis may seem to be the more attractive option, because it is less costly and less time-consuming than complete gene analysis. Another advantage specific to retinoblastoma is the availability of intragenic probes within the *RB1* locus that substantially reduce the risk of undetected recombination events. However, there is a significant source of error that makes linkage analysis less attractive for most retinoblastoma families. Mosaicism for an *RB1* mutation is common in the founding member of a retinoblastoma family. This can confound the results of linkage analysis, creating the impression that the offspring of a mosaic parent, who has inherited the at-risk haplotype, are at risk of retinoblastoma when in fact that is not the case. Such a false-positive result could be devastating if linkage analysis were used for prenatal diagnosis purposes. To exclude the possibility of false positives due to undetected mosaicism, only very large pedigrees should be considered for linkage analysis. Ideally, the affected founder of a retinoblastoma family and any of his or her unaffected offspring should be excluded from the analysis.

### 140.8.8 Segregation Ratios in Offspring of Adults with Sporadic Bilateral Retinoblastoma

Mendelian segregation ratios dictate that half of the offspring of known *RB1* cancer syndrome patients will inherit the genetic defect in *RB1* from their affected

parent. About 90% of these individuals will develop retinoblastoma in one or both eyes. This is true when the parent's disease was due to an inherited gene defect passed on from an affected grandparent. Surprisingly, however, this is not the case for affected males with a new mutation. Among the offspring of males with bilateral sporadic disease, there is a sex ratio distortion that favors male offspring as well as a transmission ratio distortion that favors affected males (109).

Among all new cases of bilateral disease, there is also an excess of affected males. These observations are difficult to explain without invoking another underlying defect that affects the viability of female and male fetuses. Such an explanation was proposed by Naumova and Sapienza, who speculated that, in a certain percent of retinoblastoma (and by extension probably all) families, co-inheritance of a maternally inherited X-linked defect in imprinting affects a male's ability to erase the maternal imprint in the chromosomes he passes on (109). Thus female offspring from these males with two maternally imprinted X chromosomes would be nonviable. The observed excess of male offspring would in fact be due to a paucity of female offspring. This could explain the sex ratio distortion seen in many families, including those with retinoblastoma.

Since in this scenario most of the surviving fetuses would be male, it is also pertinent to this theory that the retinoblastoma gene is located on an imprinted chromosome 13. A man would transmit his maternally inherited chromosome 13 (which would not usually carry the new mutation for retinoblastoma) without erasing that maternal imprint. The resulting fetus, with two copies of chromosome 13, bearing a maternal imprint and unaffected by retinoblastoma, would not survive. A fetus would be viable when it inherited its father's paternally imprinted chromosome 13, the paternally derived chromosome 13 that usually contains the initial *RB1* mutation in a sporadic case. This viable fetus would also therefore be affected with retinoblastoma. In this situation, the retinoblastoma phenotype would be a marker for the grandpaternally inherited and properly imprinted chromosome 13. This explains the transmission ratio distortion seen in the offspring of males with sporadic bilateral retinoblastoma.

To date, this elegant theory, although persuasive, has not found a practical application in retinoblastoma genetic counseling. It is, however, useful to know that the typical Mendelian segregation ratios of affected and unaffected offspring and affected males and females may not apply to all families of males with sporadic bilateral retinoblastoma.

### 140.8.9 Clinical DNA Testing: Commercial Laboratories Offering DNA Testing

All *RB1* testing must be carefully coordinated so tumor and blood DNA specimens from the patient are collected

appropriately (110). The Internet is a helpful resource for those seeking genetic testing centers for retinoblastoma. GeneTests ([www.genetests.org](http://www.genetests.org)) provides updated information about many disorders, including retinoblastoma. A comprehensive review of pertinent clinical testing and counseling issues is available, as is a database of commercial and research laboratories that offer genetic testing for *RB1*. Another site, eyeGENE, provides free genetic testing for all inherited eye diseases including retinoblastoma. The genetics clinician or counselor must communicate directly with the laboratory before sending any samples. The costs, sample preparation, and detection rate vary with each laboratory.

## 140.9 APPROACHES TO PRENATAL ASSESSMENT AND DIAGNOSIS

### 140.9.1 Pre-implantation Genetic Diagnosis

The ability to provide testing of at-risk pregnancies has been available since the early 1990s (111,112). These include heritable cancers such as adenomatous polyposis coli, BRCA1, Li-Fraumeni syndrome, and von Hippel-Lindau syndrome, as well as Fanconi anemia and Wiskott-Aldrich syndrome (113). A method for detection of a known mutation in PGD of retinoblastoma was reported in 2000 (114). It was first reported as being used in the prenatal diagnosis of pregnancies at 50% risk of retinoblastoma in 2003 by Girardet and colleagues, who evaluated the amplification efficiency and allele dropout rates for two highly polymorphic microsatellite markers located within and close to *RB1*, respectively (115). Xu and colleagues subsequently reported the first liveborn after PGD for retinoblastoma in 2004 (116). This means of screening embryos for retinoblastoma was approved in Great Britain in 2005 (117).

PGD requires prior knowledge of the mutation in *RB1*. In in vitro fertilization (IVF), when the embryo is at the 8- to 10-cell stage, a blastomere, one cell from the developing embryo, is removed for genetic testing while the remaining mass of cells is returned to incubation. Those embryos not containing the mutation are deemed unaffected, and one or two, optimally, are implanted in the mother's uterus. Others that are unaffected may be frozen for future use. Due to the inaccuracies inherent in PGD, most protocols require that an amniocentesis be performed for prenatal diagnosis during the pregnancy to confirm the molecular analysis results and for cytogenetic analysis.

### 140.9.2 Concern Regarding Assisted Reproductive Technologies

Evidence is accumulating that assisted reproductive therapies (ART) may be associated with increased epigenetic disorders in babies conceived using these procedures. This has been reported in ART associated with an increased

incidence of Beckwith-Wiedemann syndrome and Angelman syndrome, for example. Epigenetic reprogramming is active during gametogenesis and at preimplantation and involves DNA methylation, imprinting, RNA silencing, covalent modifications of histones, and remodeling by other chromatin-associated complexes (118). Moll and colleagues report five patients diagnosed with retinoblastoma in the Netherlands between November 2000 and February 2002, all after IVF (119). The calculated relative risk of retinoblastoma is 7.2 for an IVF rate of 1% (95% CI, 2.4–17.0) or 4.9 for an IVF rate of 1.5% (95% CI, 1.6–11.3). Ben Ezra suggests that these five cases could represent clustering of cases reported by interested observers and one should use caution in assuming that IVF was the cause of the retinoblastoma (27).

### 140.9.3 Prenatal Genetic Diagnosis without PGD

Couples may elect to have prenatal genetic diagnosis without using PGD; this may be chosen if finances do not permit PGD or the family wishes to know the diagnosis but does not wish to intercede in the pregnancy. When the mutation is known, prenatal diagnosis can be performed via chorionic villus sampling or amniocentesis.

### 140.9.4 Fetal Ultrasound and Magnetic Resonance Imaging

Improved fetal imaging, fetal ultrasound, and fetal MRI add to the tests available for the diagnosis of prenatal retinoblastoma. Fetal ultrasound and fetal MRI are complementary technologies in the evaluation of fetal abnormalities. Ultrasound is widely available, relatively inexpensive, and safe, and it allows for real-time imaging (120). Ultrasound is limited, however, in women who are obese and in women whose pregnancies have reduced amniotic fluid. In addition, in later gestation it is difficult to evaluate intracranial anatomy through the more ossified fetal skull. Fetal position may also limit utility. The use of MRI in the fetus provides more standardized results and a larger field of view can be seen. With the advent of fast imaging techniques, MRI has been used to evaluate fetal anomalies since the mid-1990s (21). However, MRI has its own limitations including expense, claustrophobia on the part of the mother, and less spatial resolution. Most commonly, MRI has been used to evaluate central nervous system abnormalities, which in some centers have been found to influence or change management and counseling in up to 50% of cases (121). Some images can be seen in Figures 140-17–140-20.

### 140.9.5 Factors Associated With Increased Risk of Sporadic Retinoblastoma

In studies of parental age and parity, it has been shown that there is a correlation between sporadic hereditary

**FIGURE 140-17** This child has an ocular prosthesis following enucleation for advanced unilateral retinoblastoma. The surgical removal of an eye for the definitive treatment of retinoblastoma can have very little impact on the cosmetically 'normal' appearance of a child. Enucleation without radiotherapy does not result in facial and bony deformity. Meticulous surgery and the use of as large an orbital implant as possible makes this treatment alternative a very attractive one, especially when advanced unilateral disease is present.

**FIGURE 140-18** This image is a fetal transabdominal ultrasound of the orbit at 20 weeks' gestation. Gray drawing designated by arrow represents what a 1-mm in height mass may look like. The dashed line represents how much a 2-mm lesion would protrude into the vitreous. (Image courtesy of David Miller, M.D., and Lisa Paquette, M.D.).

retinoblastoma and parental age. I Sivakumaran and colleagues demonstrated familial retinoblastoma was significantly associated with early para (52). Mean paternal age of sporadic bilateral cases was significantly higher than that of sporadic unilateral cases. There was no correlation with mean maternal age, so the conclusion was that advanced paternal age is associated with sporadic bilateral retinoblastoma. Dockerty and colleagues performed a case-control study of childhood cancers with regard to parental age, parity, and social class (122). Their results demonstrated that the odds ratio (OR) for retinoblastoma resulting from apparent new germ cell mutations among children of fathers age 45 or older was 3.0 (95% CI, 0.2–41.7).

As discussed earlier in this chapter, Orjuela and colleagues examined fruit and vegetable intake during pregnancy and risk of development of sporadic retinoblastoma (89). Using dietary recall questionnaires, these authors studied mothers of 101 children with retinoblastoma and 172 control mothers. The risk of having a child with retinoblastoma was increased for mothers consuming fewer than two daily servings of vegetables (OR 3.4; 95% CI, 2.0–6.0) or with a low intake of folate (OR 3.9; 95% CI, 2.1–7.3) or lutein/zeaxanthin (OR 2.6; 95% CI, 1.5–4.6) derived from fruits and vegetables.

## 140.10 CONCLUSIONS

Retinoblastoma has played a pivotal in our understanding of the molecular genetics associated with tumorigenesis. This has led to improved screening and treatment options for patients and families. A thorough understanding of the genetics associated with retinoblastoma is critical for any practitioner who manages this disease. Today a genetics assessment is the standard of care for all families with retinoblastoma. Patients, parents, siblings and offspring benefit from this type of counseling. In the future, improved screening and directed treatments will translate into further reduction in patient and ocular morbidity.

## Anophthalmia, Microphthalmia, and Uveal Coloboma

*Brian P Brooks*

Ophthalmic Genetics and Visual Function Branch, National Eye Institute, Bethesda, MD, USA

### GLOSSARY

- Anophthalmia** – absence of ocular tissue, most often on clinical examination
- Coloboma** – a general term implying a congenital loss of tissue in or around the eye
- Microphthalmia** – small eye; technically defined as have an axial length less than two standard deviations from the age-adjusted mean
- Optic cup** – a two-layered bilateral concave neuroepithelial structure that develops from the optic vesicle as it approaches the surface ectoderm
- Optic fissure** – a transient opening on the ventral surface of the optic cup that must close during the 5th to 6th week of human gestation in order for the eye to form a spherical structure
- Optic vesicle** – a bilateral evagination of the rostral neural tube that is the first major morphologic change in eye development
- Uveal coloboma** – a ventral defect in the iris, ciliary body, neural retina/retinal pigment epithelium/choroid, and/or the optic nerve caused by failure of the optic fissure to close

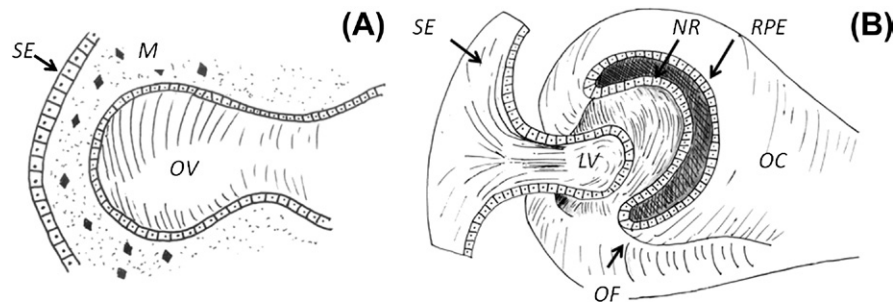

### 141.1 INTRODUCTION

The purpose of this chapter is to review several congenital ocular malformations—namely anophthalmia, microphthalmia, and coloboma—that are likely to be encountered in a clinical medical genetics practice. Emphasis will be placed on clinical diagnosis, molecular genetics, and developmental mechanisms. Readers are referred to Chapters 135, 136, 137, and 138 in this text for discussion of infantile cataracts, infantile glaucoma, infantile corneal abnormalities, and early-onset retinal degenerations.

Ocular malformations may have genetic and non-genetic (e.g. environmental) causes. Inherited ocular malformations may appear as familial or sporadic and they may be isolated or associated with a broader syndrome.

While significant strides have been made on understanding the developmental and genetic basis of these abnormalities, frequently no specific cause can be determined for a given malformation. Depending on the method of ascertainment, the population studies, and the definition of “ocular malformation,” published studies have found a birth prevalence of ocular malformations of 0.04–6.8/10,000 live births (1–7).

In order to understand the developmental mechanisms responsible for ocular malformations, it is helpful to briefly review early ocular development (8). During the fourth week of human gestation, rostral evaginations of the neuroectoderm (the optic vesicle) form bilaterally (Figure 141-1). The optic vesicle remains connected to the developing brain via the optic stalk, the primordium of the optic nerve. As this one-cell-thick sheet of neuroepithelium approaches the overlying surface ectoderm (SE), the distal optic vesicle invaginates to form a bilayered optic cup (OC), with the presumptive neural retina forming the inner layer and the presumptive retinal pigment epithelium (RPE) forming the outer layer. The invagination of the optic cup (OC), however, is asymmetric, such that there is a ventral gap (the optic fissure (OF)), which allows for periorbital mesenchyme that will form the primordial ocular vasculature to invade the developing eye and optic nerve. Beginning approximately in the fifth week of human gestation, the two edges of the OF approximate and fuse to form a circumferentially continuous OC. Coincident with the formation of the OC, the SE overlying the developing eye is induced to thicken into the lens placode. This specialized ectoderm then invaginates and detaches from the SE to form the lens vesicle (LV), the primordium of the crystalline lens. Around the time of OF closure, the cells of the presumptive neural retina adjacent to the optic stalk begin to differentiate into retinal ganglion cells. The optic nerve begins developing as these retinal ganglion

**FIGURE 141-1** Schematic of early ocular development. The eye develops as an evagination of the developing forebrain, called the optic vesicle (A). As the optic vesicle approaches the SE, the single layer of neuroepithelium invaginates to form the OC (B). The inner layer of this neuroepithelium is the presumptive neural retina, while the outer layer is the presumptive RPE. Formation of the OC is coincident with the invagination of the SE to form the LV. This invagination is asymmetric, such that there is a gap along the ventral surface of the OC called the OF. The edges of the fissure normally meet and fuse between the 5th and 6th weeks of human gestation; failure of OF closure leads to uveal coloboma.

cells send their axons through vacuolized areas of the optic stalk and into the developing brain (9,10). This differentiation process continues to move more peripherally through subsequent weeks of development. All these developmental processes are precisely orchestrated in space and time via a complex network of growth factors, transcription factors, and guidance molecules.

## 141.2 ANOPHTHALMIA, MICROPTHALMIA, AND UVEAL COLOBOMA

“Anophthalmia” implies the complete absence of ocular tissue. Patients who may appear anophthalmic clinically, may—on histologic and/or radiologic screening—have ocular remnants such as neural retina or lens tissue present. As such, anophthalmia likely lies on a phenotypic continuum with microphthalmia (small eye), leading to terms such as “true anophthalmia,” “extreme microphthalmia” (11), and “clinical anophthalmia” (12) in the literature.

Anophthalmia may be unilateral or bilateral and is often associated with short palpebral fissures and small orbits (Figure 141-2A). The developmental mechanisms for anophthalmia are incompletely understood but may include: (1) early eye patterning defects; (2) failure of the optic vesicle to form, perhaps due to reduced cell division of neural progenitor cells; and/or (3) regression of ocular structures that are initially formed.

The prevalence of anophthalmia may depend on the population studied (4), ranging from 0.2 to 0.4 per 10,000 live births in Western countries (7,13). Some reports group microphthalmia with anophthalmia. Gogate et al. have estimated that anophthalmia and microphthalmia comprise 41% of blindness in Maharashtra, India, but this is probably much larger than actual numbers in most countries (14).

Anophthalmia may be isolated or part of a broader syndrome (15). In isolated cases, inheritance may be autosomal dominant (AD) (16) or autosomal recessive (AR) (12). Note that in families with clear mendelian

inheritance, ocular pathology may be asymmetric or even unilateral. While some patients with syndromic forms of anophthalmia/microphthalmia often have delayed development and/or mental retardation, this is not always the case.

Reconstructive surgery, such as the use of spherical implants, orbital osteotomies, bone grafts, and/or orbital expanders, may improve the appearance of patients with anophthalmia (17). Serial expanders and buccal mucous membrane grafts may aid in conjunctival sac reconstruction. Lid reconstruction may require skin grafts and/or tissue flaps.

A microphthalmic eye is an eye that is two standard deviations below the age-adjusted mean axial length (18). Microphthalmia includes a range of phenotypes. Weiss has broadly broken microphthalmia into two categories—simple and complex (19,20). Simple microphthalmia refers to a small but otherwise structurally normal eye (Figure 141-2B), whereas complex microphthalmia refers to a small eye with other congenital ocular abnormalities (e.g. coloboma, cataract, or sclerocornea). Not all authors follow this convention in describing patients and some use the more general term “microphthalmia” rather than distinguish between these two subgroups. While we follow this distinction here, it is likely that “simple” and “complex” microphthalmia represent points along a phenotypic continuum in which anophthalmia is the most severe manifestation.

Simple microphthalmia may sometimes be used synonymously with the term “nanophthalmos,” especially when such eyes develop angle closure glaucoma due to anterior segment crowding and/or uveal effusions. The posterior segment of simple microphthalmic eyes is often proportionately shorter than the anterior segment (“posterior microphthalmia”) (19,21). Simple microphthalmia/nanophthalmos can be part of a systemic syndrome (e.g. the oculo-dento-digital syndrome, mucopolipidosis type III (22), and Kenny’s syndrome (23)), or inherited as an isolated trait. Yamani et al. have found that the sclera of nanophthalmic eyes contains irregularly arranged collagen lamellae, absence of elastic fibers, and abnormal

**FIGURE 141-2** (A) Patient with clinical anophthalmia due to a *SOX2* mutation, and (B) a patient with simple microphthalmia. (Pictures are courtesy of Dr Adele Schneider, Albert Einstein College of Medicine, Philadelphia, PA.)

glycogen-like deposits (24). This abnormal tissue architecture is accompanied by a decrease in scleral elasticity and an increase in scleral thickness, which may reduce blood flow through vortex veins and/or decrease trans-scleral flow of protein. It is likely that this abnormal fluid dynamics in the nanophthalmic eye contributes to the increased risk of uveal effusions and choroidal detachment, particularly after surgery (25–28). Sener et al. found that strabismus, particularly non-accommodative and refractive esotropia, was common in patients with nanophthalmos and that surgical dosing of muscle recessions did not have to be altered because of the small eyes of these patients (29). “Amblyopia,” they found, can also be refractory to treatment, perhaps because some of these patients may actually have subtle foveal hypoplasia on optical coherence tomography and an abnormal foveal avascular zone on angiography (30). Khan and Zafar have noted retinal degenerative and pigmentary changes in a subset of patients with nanophthalmos (31).

In 1998, Othman et al. mapped a locus (*NNO1*) for AD nanophthalmos to a 14.3-kb region on 11p (Online Mendelian Inheritance in Man (OMIM) #600165) (32). In this cohort, 22 patients were affected with high hyperopia (refractive error +7.25 to +13.00 D) and short axial lengths (17.55–19.28 mm). Of these, 12 had either a history of angle closure glaucoma or occludable anterior chamber angles on examination. More recently, Li et al. mapped a second AD nanophthalmos locus (*NNO3*) to 2q11–q14 in a Chinese family (OMIM #611897) (33). In addition to nanophthalmos, affected members of the family had enophthalmos, narrow palpebral fissures, mild ptosis, shallow anterior chambers, microcornea, and normal pupils. Hypermetropia ranged from +6.00 to +11.25 D.

AR nanophthalmos (OMIM #609549, also *MCOPS5*, #611040) has also been reported in an Amish family (34) to result from a mutation of the *MFRP* gene (OMIM #606227), which encodes a frizzled-related protein (35).

The phenotypic spectrum of this disorder has been extended by Ayala-Ramirez et al. and Crespi et al. to include retinal degeneration, foveoschisis, and optic disc drusen (36,37).

Complex microphthalmia refers to an eye that is small and accompanied by other congenital ocular malformations, such as uveal coloboma or persistence of the fetal vasculature (PFV). Like simple microphthalmia, complex microphthalmia can be isolated or part of a genetic syndrome. Loci/genes for both isolated and syndromic microphthalmia have been identified (Table 141-1) (38–58). Complex microphthalmia is sometimes observed in children with chromosomal abnormalities, most notably Wolf–Hirschhorn (4p-) syndrome, trisomy 13, cat eye syndrome, and 13q deletions (59,60). The most common form of syndromic microphthalmia is CHARGE syndrome (see Section 141.3.3). Because microphthalmia has been associated with over 100 different syndromes, an extensive review of the literature is beyond the scope of this text. However, selected prominent syndromes are detailed below.

### 141.2.1 Uveal Coloboma

The OF is a transient opening on the ventral surface of the developing OC that allows for the migration of periocular mesenchyme into the eye. Beginning approximately at 5 weeks of human gestation, the edges of the OF appose and fuse in order that the globe becomes a complete sphere. Failure of the OF to close results in uveal coloboma (61,62). The term “coloboma” has been used somewhat loosely in the ophthalmic literature to mean a developmental abnormality in or around the eye where a piece of tissue appears to be missing—hence the terms such as “eyelid coloboma” associated with Goldenhar syndrome or “macular coloboma” associated with Leber congenital amaurosis. Perhaps the most confusing

TABLE 141-1 Reported Loci/Genes for Microphthalmia

<i>MCOPS9</i>	#601186	15q24.1 ( <i>STRA6</i> )	AR	Matthew–Wood syndrome, diaphragmatic hernia with pulmonary hypoplasia, CHD, IUGR
<i>MCOPS10</i>	%611222		AR (?)	Microcephaly, progressive spasticity, seizures, mental retardation

Although many genes are associated with complex microphthalmia, at least two have been associated with simple microphthalmia. Note that although some loci are designated as “nonsyndromic,” systemic abnormalities have been reported in some of these patients. AD = autosomal dominant; AR = autosomal recessive; CHD = congenital heart disease; GU = genitourinary; IUGR = intrauterine growth abnormalities; MCOP = microphthalmia, nonsyndromic; MCOPCB = microphthalmia, isolated with coloboma; MCOPCT = microphthalmia, isolated, with cataract; MCOPS = microphthalmia, syndromic; XL = X-linked.

term is “optic nerve coloboma,” as this can refer to a uveal coloboma that affects the optic nerve, a congenital excavation of the optic nerve, or the morning glory disc anomaly. In this chapter, we will reserve the word “coloboma” to refer to conditions related to OF closure.

Uveal coloboma may accompany complex microphthalmia, but not all eyes with coloboma are microphthalmic. Similarly, many eyes with coloboma have small corneas (microcornea). Microcornea may exist, however, independent of coloboma and coloboma may exist independent of microcornea. When coloboma affects the anterior segment, the pupil appears

teardrop-shaped, pointing inferonasally (the direction of the OF, [Figure 141-3A](#)). If the coloboma extends slightly more posterior, it may affect the ciliary body and result in absent zonules in the inferonasal quadrant. The focal absence of zonules leads to focal flattening of the lens curvature, sometimes referred to as a “lens coloboma” ([Figure 141-3B](#)). This abnormality may result in significant astigmatism that should be optically corrected in children to avoid amblyopia. When a coloboma extends further posteriorly, it appears as a defect in the neural retina, RPE, and choroid, revealing bare sclera ([Figure 141-3C, D](#)). Sometimes these areas

**FIGURE 141-3** The clinical appearance of uveal coloboma. (A) Uveal coloboma of the iris appears as a teardrop-shaped pupil pointing inferiorly and nasally—the position of the OF. (B) Uveal coloboma affecting the ciliary body can lead to a defect in lens zonules, resulting in a focal flattening of the peripheral curvature of the crystalline lens—a so-called lens coloboma. This defect can lead to astigmatism and, in children, amblyopia. (C) Uveal coloboma that affects the posterior pole appears as a patch of bare sclera in the inferonasal quadrant. Because this coloboma does not involve the optic nerve and/or macula, the vision of this patient is normal. (D) Uveal coloboma can extend posteriorly to involve the optic nerve and macula. In such cases, the optic nerve is frequently small and dysplastic. Although visual prognosis is often guarded, attempts to improve vision with glasses and/or amblyopia treatment should still be attempted.

of colobomatous defects are focal and circumscribed; sometimes there are “skip areas” unaffected by the coloboma. Hyper- and hypopigmentation around the edges of the coloboma are common. When the coloboma extends posteriorly enough to involve the optic nerve and/or macula, vision can be affected. Maumenee and Mitchell have estimated that approximately 10% of childhood blindness results from coloboma (63). Optic nerves affected by coloboma are often dysplastic.

Although uveal coloboma is not a progressive condition per se, the sclera overlying the defect may become more excavated with time. Retinal blood vessels may initially bridge the surface of a coloboma. Over time, this stretching of the coloboma area may lead these vessels to bleed, resulting in a vitreous hemorrhage. In addition, uveal coloboma likely predisposes to retinal detachment (64,65) and choroidal neovascularization (abnormal blood vessel growth beneath the neural retina) (66) in some patients later in life. Presenile cataracts may also occur (63).

The term “microphthalmia with cyst” refers to a condition where neuroectodermal tissue protrudes through the unclosed OF to form a potential space adjacent to the developing eye. This potential space can fill with fluid, causing developmental disruption of the eye—hence, microphthalmia. Most cases are sporadic, although familial cases

have been reported (67). The cyst may push the eye superotemporally, resulting in a bulging mass behind the lower lid. Imaging of the affected orbit may show that the cyst is larger than the eye per se. The management of microphthalmia with cyst depends upon several factors: the visual potential of the eye, the growth of the cyst over time and the cosmetic appearance of the patient. Strategies include aspiration, observation, and excision (with or without enucleation) (68). In cases where enucleation is performed, socket expansion may improve the patient’s cosmetic appearance. Gupta et al. have reported on a syndrome of bilateral microphthalmia with cyst, and facial and limb anomalies (OMIM 607597) (69). Microphthalmia with cyst may be distinct from the condition “congenital cystic eye,” which likely results from failure of the optic vesicle to invaginate normally (70).

### 141.3 GENES AND SYNDROMES ASSOCIATED WITH ANOPHTHALMIA, MICROPTHALMIA, AND/OR UVEAL COLOBOMA

The nosology of anophthalmia, microphthalmia, and uveal coloboma (AMC) is complex and imperfect. In the broadest sense, AMC can be subdivided into “syndromic” and “nonsyndromic/isolated” forms, depending

on whether the developmental eye abnormalities are associated with systemic findings. While some patients may clearly fit into the “syndromic” category—for instance, patients with chromosomal abnormalities and multiple congenital anomalies—some patients may have relatively minor findings (e.g. the cutaneous syndactyly seen in some patients with mutations in *GDF6*). Approaching the patient with congenital eye anomalies therefore requires some appreciation of the continuum of phenotypes between these two extremes. Further complicating any classification scheme is the wide phenotypic spectrum reported in many patients with mutations in a developmentally regulated gene. Likely, this wide spectrum is at least partly due to noncoding sequence differences between individuals, sequence differences in other genes in the same developmental pathway, environmental factors, and stochastic factors. The major genes and syndromes associated with AMC are listed alphabetically below.

### 141.3.1 14q22–q23 Deletion Syndrome, *OTX2*, and Bone Morphogenetic Protein-4

Interstitial deletions of chromosome 14q22–23 cause a syndromic form of anophthalmia/microphthalmia, with brain, pituitary, digit, thyroid, and genital abnormalities (71). Ragge et al. found mutations in the bicoid-type homeodomain transcription factor gene, *OTX2* (OMIM #610125; *MCOPS5*), which lies in this region in series of individuals and families with a broad spectrum of phenotypes (54). Affected individuals may present with anophthalmia/microphthalmia, a retinal dystrophy resembling Leber congenital amaurosis and pigmentary retinopathy, and/or varying degrees of central nervous system pathology. Further complicating the phenotypic spectrum and the genetic counseling of such patients was apparent non-penetrance in mutation-positive individuals and gonadal mosaicism. Schilter et al. have recently proposed that the presence of pituitary anomalies and the absence of gastrointestinal manifestation may help distinguish *OTX2*-related from *SOX2*-related anophthalmia/microphthalmia (see Section 141.3.15) (72). Most mutations are predicted to result in premature truncation of the *OTX2* protein. While the predominant mechanism of disease is thought to be haploinsufficiency (73), a dominant-negative mechanism may play a role with at least some mutations (74). The presence of retinal degeneration in some patients with *OTX2* mutations may be related to its role in photoreceptor and bipolar cell development/maintenance (75,76).

The bone morphogenetic protein-4 gene (*BMP4*; OMIM #607932; *MCOPS6*) also lies within the 14q22–q23 region. *BMP* is a member of the transforming growth factor beta 1 (TGF- $\beta$ 1) family of secretory signaling molecules that play an essential role in embryonic development, including eye development (77). Mutations in the *BMP4* gene—like mutations in *OTX2*—lead to a broad spectrum of findings, including

anophthalmia/microphthalmia, retinal dystrophy, myopia, brain abnormalities, and polydactyly (55). The developmentally regulated genes *SHH* and *PTCH1* may act as modifiers of the *BMP4* phenotype. These findings, like those in patients with *OTX2* mutations, emphasize that mutations in developmentally regulated genes may result in both congenital malformations and a degenerative phenotype (e.g. retinal degeneration).

### 141.3.2 *BCOR*, Lenz Microphthalmia and the Oculofacialcardiodental Syndrome

Lenz microphthalmia (*MCOPS1*; OMIM #309800; and *MCOPS2*; OMIM #300166) is a phenotypically and likely genotypically heterogeneous, X-linked condition. In addition to (often colobomatous) microphthalmia or anophthalmia, patients may have intellectual disability and dental, ear, genitourinary, digital, and skeletal abnormalities (78). Two loci on the X chromosome, *MCOPS1* (Xq27–q28; OMIM #309800) and *MCOPS2* (Xp11.4; OMIM #300166), have been identified (51). Forrester et al. describe a pedigree mapping to Xq27–q28 that extends the phenotype to include cardiac anomalies (50). While Ng et al. identified a c.C254T (p.P85L) sequence change in the BCL-6-interacting corepressor (*BCOR*) gene in a family mapping to the *MCOPS2* locus (52), the gene responsible for the *MCOPS1* phenotype has not yet been identified. The nomenclature for Lenz microphthalmia is further complicated by the report of a family with clinical anophthalmia, preauricular skin tags, and cleft palate that maps to Xq27–q28 (*MCOPS4*; OMIM #301590), but this has been considered a distinct genetic entity (53).

Ng et al. also noted phenotypic overlap between Lenz microphthalmia and the X-linked oculofacialcardiodental syndrome (OFCD), which is lethal in males. Affected females often present with microphthalmia  $\pm$  cataracts, congenital heart anomalies, dysmorphic features (simple ears, elongated face, broad nasal tip), hammer-toe deformity, and dental abnormalities (e.g. persistent primary teeth and radiculomegaly) (79). Mutations predicted to result in *BCOR* haploinsufficiency were found in seven OFCD families, making it allelic to Lenz microphthalmia at the Xp11.4 locus. Morpholino knockdown of *BCOR* in zebra fish results in ocular, skeletal, and nervous system abnormalities, consistent with the human phenotype. In addition to describing a deletion of *BCOR* in a family with OFCDB, Horn et al. did not find any mutations in patients with Lenz microphthalmia, suggesting that the *MCOPS2* locus is a minor contributor to the Lenz microphthalmia phenotype (80).

### 141.3.3 CHARGE Syndrome

The most common cause of syndromic uveal coloboma is the CHARGE syndrome (OMIM #214800)—an acronym for coloboma (usually bilateral  $\pm$  microphthalmia),

congenital heart abnormalities, atresia or stenosis of the choanae (unilateral or bilateral), retardation of growth/development, genitourinary (including renal) abnormalities, and ear abnormalities (81). Patients may have hypomia/anosmia and hypogonadotropic hypogonadism, thus overlapping with the phenotype of Kallman syndrome. Mondini defects of the cochlea and/or absent/hypoplastic semicircular canals are found in nearly all patients on imaging. Patients may have other cranial nerve dysfunctions, including facial palsy and difficulty with swallowing. Orofacial clefting is observed in approximately 15–20% of individuals. Mutations in the chromodomain gene *CHD7* (OMIM \*608892) are found in approximately two-thirds of patients with CHARGE syndrome (82). A rare cause of CHARGE syndrome may be mutations in the *SEMA3E* gene (OMIM \*608166) (83). While the precise mechanisms by which mutations in *CHD7* result in coloboma and other systemic abnormalities is still unclear, recent evidence has supported a role of neural crest development (84), ribosomal synthesis (85) and stem cell gene expression (86).

#### 141.3.4 Growth-Differentiation Factor 3

In 2010, Ye et al. described six different missense mutations in growth-differentiation factor 3 (*GDF3* (OMIM \*606522); *MCOP7* (OMIM #613704); *MCOPCB6*, digenic (OMIM #613703)) in patients with variable microphthalmia and/or uveal coloboma accompanied by skeletal abnormalities (Klippel–Feil anomaly, vertebral fusion, scoliosis) (Figure 141-4) (87). Some individuals had both skeletal and ocular abnormalities, while others had one but not the other. In one case, an individual had a mutation in both *GDF3* and *GDF6*, raising the possibility that phenotypic variability may in part be explained by the “mutation load” in this gene family. *GDF3* is a member of the TGF- $\beta$ 1/bone morphogenetic protein family of growth factors that may also have *NODAL*-like activity (88–90).

#### 141.3.5 Growth-Differentiation Factor 6

Asai-Coakwell et al. identified a patient with an interstitial deletion of chromosome 8 (46,XX,del(8)(q21.2–q22.1)) with chorioretinal uveal colobomas, an atrial-septal defect, soft tissue syndactyly, and developmental delay (42). Included in this deletion interval is the growth-differentiation factor 6 (*GDF6*; *MCOP4* (OMIM #613094); *MCOPCB6*, digenic (OMIM #613703)), a member of the TGF- $\beta$ 1 family of growth factors. A subsequent screen of 489 patients with anophthalmia/microphthalmia/coloboma identified several different missense mutations (91). Klippel–Feil anomaly of the spine is observed in a subset of these patients, where incomplete penetrance and variable expressivity are common. Functional studies in vitro and in model organisms support a role of *GDF6/Gdf6/gdf6* in ocular

**FIGURE 141-4** Klippel–Feil anomaly of the cervical spine in a patient with a *GDF3* mutation. (Photo is courtesy of Dr Ordan Lehmann, University of Alberta, Edmonton.)

and skeletal development (92,93). A systemic screen of 50 patients with anophthalmia/microphthalmia/coloboma for mutations in *GDF6*, *OTX2*, *CHX10*, *RAX*, and *SOX2* found the highest prevalence of mutations in *GDF6* (8%) (94).

#### 141.3.6 HCCS, MIDAS Syndrome

MIDAS syndrome (microphthalmia, dermal aplasia and sclerocornea; *MCOPS7*; OMIM #309801) is an X-linked syndrome associated with unilateral or bilateral microphthalmia and linear, aplastic skin lesions, generally limited to the head and neck (95,96). With the exception of XX males (97,98), all reported cases have been in females, suggesting that this syndrome is lethal for males in utero. Numerous cytogenetic abnormalities leading to MIDAS syndrome have been reported in the region of Xp22 (95,99,100). Although there is some phenotypic overlap, MIDAS is genetically distinct from Golz syndrome (focal dermal hypoplasia (OMIM #305600), *PORCN* gene (OMIM \*300651)) and incontinentia pigmenti (OMIM #308300; *IKBK/NEMO* \*300248). In 2006, Wimplinger et al. identified one nonsense mutation (p.R197X) and one missense mutation (p.R217C) in the mitochondrial holocytochrome c-type synthase gene (*HCCS*; OMIM \*300056) (56). This enzyme acts as a heme lyase by covalently linking a

heme prosthetic group to cytochrome c and cytochrome c1. In addition, this group identified a mother–daughter pair who had a submicroscopic 8.6-kb deletion that involved the *HCCS* gene. These findings raise the interesting notion that mitochondrial genes may play a role in development (perhaps by regulating apoptosis) as well as their more established role in cellular energy metabolism.

### 141.3.7 *HMX1* and the Oculoauricular Syndrome

Studying the descendents of a consanguineous Swiss family originally described by Franceschetti and Valerio, Schorderet et al. identified a heterozygous 26-bp deletion in the *HMX1* transcription factor gene (OMIM \*142992, previously known as *NKX5-3*) (101). Affected individuals have congenital external ear abnormalities (with normal hearing) and a range of congenital ocular abnormalities including microphthalmia, microcornea, cataracts, iris adhesions to the lens and cornea, abnormal electroretinograms, and dysplastic optic nerves (oculoauricular syndrome; OMIM #612109). *HMX1* codes for a homeobox transcription factor protein expressed in the developing eye and ear. Knockdown of the zebra fish ortholog leads to microphthalmia and abnormal retinal lamination. The mouse mutant, Dumbo, results from a nonsense mutation in the *Hmx1* gene, which leads to high perinatal lethality, small size, abnormally positioned pinnae, and microphthalmia (102).

### 141.3.8 *MAF*

Using a family in whom a chromosome translocation, t(5; 16)(p.15.3; q23.2), cosegregated with anterior segment dysgenesis, cataract, and microphthalmia in both balanced and unbalanced forms, Jamieson et al. determined that the breakpoint disrupted the leucine zipper transcription factor gene, *MAF* (OMIM \*177075) (103). In addition, they identified a second family that exhibited AD pulverulent cortical and (later) posterior subcapsular cataract who had a missense mutation in a well-conserved residue in the DNA-binding domain of this gene (R288P, OMIM #610202). Two members of this family had microcornea and one had bilateral iris colobomas. Homozygous *Maf*<sup>−/−</sup> mice show cataract and microphthalmia, consistent with the human phenotype (104).

### 141.3.9 *PAX6*

The paired-box and homeodomain-containing transcription factor gene, *PAX6* (OMIM \*607108), plays a central role in ocular development. *PAX6* mutations are most often case aniridia (OMIM #106210)—an AD panophthalmic disease of ocular development characterized by iris hypoplasia, nystagmus, foveal hypoplasia, limbal stem cell deficiency, cataracts, and glaucoma

(105,106). Milder anterior segment phenotypes have also been described (OMIM #136520) (107,108). Although mutation of *Pax6* causes microphthalmia in mouse (109) and rat (110) models, *PAX6* mutations do not appear to be a major cause of microphthalmia/anophthalmia in humans. In a national study of anophthalmia, microphthalmia, and coloboma in Scotland, Morrison et al. noted no mutations in *PAX6* in 84 patients (3). However, rare cases of anophthalmia and congenital brain anomalies associated with mutations of both alleles of *PAX6* have been reported (111). Azuma et al. reported a patient with mental retardation, a complex developmental eye abnormality including uveal coloboma, and a *PAX6* missense mutation (F258S) (112).

### 141.3.10 Retina and Anterior Neural Fold Homeobox Gene

The retina and anterior neural fold homeobox gene (*RAX/RX* (OMIM \*601881); *MCOP3* (OMIM #611038)) is an evolutionarily conserved homeodomain gene that is essential for normal eye development (113). In mice, knockout of *Rax* function leads to failure of OC formation and anophthalmia. Other developmentally important genes such as *OTX2* and *SOX2* regulate *RAX* expression (114). Vororina et al. screened 75 individuals with anophthalmia or microphthalmia and found one boy with microphthalmia, sclerocornea, and autism who was a compound heterozygote for a Q147X nonsense mutation and a R192Q mutation, both within the DNA-binding domain of *RAX* (41). Although at least one other case of *RAX* mutation in anophthalmia has been reported (115), the prevalence of *RAX* mutations in patients on the AMC spectrum appears to be low (116).

### 141.3.11 *SIX3*

Mutations in the homeodomain gene *SIX3* (OMIM \*603714) cause holoprosencephaly (failure of the brain to develop into two complete, separate hemispheres) in humans, sometimes with ocular abnormalities such as microphthalmia and/or coloboma (117). Although lower vertebrate orthologs of *SIX3* are important in ocular development (118)—the designation “SIX” means “ortholog to *Drosophila sine oculis*”—the prevalence of *SIX3* mutations in nonsyndromic AMC patients appears to be low (3,119).

### 141.3.12 *SIX6*

*SIX6* (OMIM \*606326; *MCOPS6*; OMIM #607932), another member of the *SIX* family of homeodomain genes, has a sequence highly homologous to that of *SIX3* and is expressed in the developing retina and ventral optic stalk (120). As previously noted, interstitial deletions involving 14q23—where *SIX6* is located along with *OTX2* and *BMP4*—have been reported in individuals

with anophthalmia/microphthalmia and pituitary abnormalities (121,122). In 2004, Gallardo et al. identified a single missense mutation (T165A) in a patient with bilateral microphthalmia, nystagmus, and cataract (49); however, this sequence change was also observed in the patient's unaffected father. Aijaz et al., however, failed to identify any mutations in *SIX6* in 173 patients with AMC (123), raising the possibility that other genes in the 14q23 interval are likely responsible for the ocular and pituitary abnormalities in these patients.

### 141.3.13 Sonic Hedgehog

Sonic hedgehog (SHH) is an extracellular signaling molecule that is critical in multiple developmental processes (124), including the development of normal retinal lamination (125). Mutation of *SHH* (OMIM\*600725; *MCOPCB5*; OMIM #611638) in humans is generally associated with holoprosencephaly (126,127). Shh knockout mice exhibit cyclopia with abnormal retina-RPE patterning (128). SHH regulates the paired homeobox gene, *Pax2* (129,130), which is critical for OF closure in mice. Schimmenti et al. screened 53 probands with colobomatous microphthalmia for mutations in *SHH* and identified a novel 24-bp deletion that co-segregated in a two-generation family in which the proband had bilateral uveal colobomas. His mother, who has the same mutation, exhibited what is likely a *forme fruste* of coloboma (47).

### 141.3.14 *STRA6* ("Stimulated by Retinoic Acid 6")

Pasutto et al. reported a form of syndromic anophthalmia accompanied by a spectrum of congenital malformations including congenital heart defects, diaphragmatic hernia, alveolar capillary dysplasia, lung hypoplasia, and mental retardation (58,131). These patients have mutations in the *STRA6* gene (OMIM \*610745; *MCOPS9*; OMIM #601185), a member of the "stimulated by retinoic acid" genes. *STRA6* functions as a membrane receptor that mediates cellular uptake of vitamin A via the retinol-binding protein (132). This constellation of findings has overlap with the previously described "Matthew-Wood" syndrome (anophthalmia with pulmonary hypoplasia) (133). Although Golzio et al. did not find pathogenic mutations in a patient with Matthew-Wood syndrome, they reported truncating mutations in two fetuses with this syndrome (134). Vitamin A and its derivatives have major roles in the growth and differentiation of multiple embryonic tissues (135).

### 141.3.15 *SRY-BOX2* (*SOX2*)

Fantes et al. found that a child with bilateral anophthalmia and a cytogenetically balanced chromosomal translocation (46,XX,t(3; 11)(q27; p11.2)) had a deletion that eliminated the *SOX2* gene (OMIM \*184429; *MCOPS3*;

OMIM #206900) on chromosome 3 (136). Furthermore, four of eleven subjects with sporadic anophthalmia had *SOX2* nonsense mutations. Subsequently, other mutations, including deletions of the *SOX2* gene, have been reported (137–140). Hagstrom et al. note that *SOX2* mutations can cause not only anophthalmia, but also aplasia of the optic nerves, chiasm, and tracts (138). Mutation of *SOX2* generally produces a fairly severe, bilateral ocular disease and can be accompanied by brain malformations, learning disability, seizures, esophageal atresia, motor abnormalities, hypogonadotropic hypogonadism, male genital tract malformations, renal abnormalities, mild facial dysmorphism, and postnatal growth failure (141,142). *SOX2* mutations likely account for the largest proportion of the monogenic causes of anophthalmia/microphthalmia described to date.

*SOX2* codes for a member of SRY-like family of the high-mobility group (HMG) of transcription factors and lies within an intron of a non-expressed gene, *SOX2OT*. It is expressed in neuroectoderm early in development (143) and is important in maintaining self-renewing progenitor cells (144). (In fact, *SOX2* is one of the critical transcription factors used currently to create induced pluripotent stem cells (iPS cells) from differentiated cells (145).) Loss of *SOX2* function may result in an abnormally early exit of neural/ocular progenitor cells from their undifferentiated state, resulting in an overall loss of neural/ocular tissue. In addition, the transcription factors *SOX2*, *PAX6*, and *OTX2* display a complex network of interactions in ocular development and/or tissue maintenance (146), suggesting that *SOX2*-related phenotypes may also result from events later in development.

### 141.3.16 *VSX2* (*CHX10*)-Related Microphthalmia

The homeobox-containing transcription factor gene *VSX2* (*CHX10*; *MCOPCB3* (OMIM #610092); *MCOP2* (OMIM #610093)) has a critical role in the development of the neural retina (147). A nonsense mutation in the murine *Chx10* gene causes the microphthalmia, thin/hypocellular retina, and optic nerve aplasia found in the *ocular retardation* mouse (148). Studying a consanguineous Turkish pedigree with colobomatous microphthalmia and infantile cataract, as well as an Arab child with microphthalmia and no discernible pupil, Percin et al. found two independent homozygous mutations in the human *VSX2* (*CHX10*) gene (40). The prevalence of mutations in *VSX2* (*CHX10*) in patients with isolated anophthalmia/microphthalmia appears to be low in other populations (3,94).

## 141.4 A CLINICAL APPROACH TO THE PATIENT WITH AMC

Given the phenotypic and genotypic heterogeneity of patients with AMC, defining a routine approach to a

patient is difficult, if not impossible. What follows is based on the personal experience of the author.

In the setting of a newborn with AMC, the first distinction to make is between a “syndromic” and “nonsyndromic” or “isolated” phenotype. A careful examination of the child for any dysmorphic features is a reasonable first step. Further clinical work-up is, in part, dictated by the clinical exam. Patients who do not pass their newborn hearing screening must be carefully followed up. Even those who *do* pass their screening may require more detailed hearing testing later in life, if for no other reason other than to maximize the possibility for auditory learning in a child who may be visually compromised. Patients with an unexplained heart murmur may benefit from an echocardiogram. Patients with low tone, microcephaly, or other neurologic symptoms may require neurologic examination and/or neuroimaging. Renal ultrasound is a reasonable noninvasive screening test that does not require radiation. The clinical approach to an older child or adult with AMC can be informed by such factors as their cognitive development and physical symptoms/exam.

In providing recurrence risk counseling, a careful eye exam of the child’s first-degree relatives is important, as “microforms” of coloboma (Figure 141-5) and subclinical simple microphthalmia may occasionally be present and could influence genetic counseling. Morrison et al. found an approximately 10% empiric sibling recurrence risk in their cohort of AMC patients (3). While this is a helpful number, it may not directly change the genetic counseling for a specific, individual family; the sibling recurrence risk found in this study combines data from “high risk” and “low risk” families. Because—in the absence of other abnormalities in the family and/or

a defined syndrome in the proband—we currently have no good way to distinguish “high risk” from “low risk” families, we counsel that there is up to a 25% recurrence risk of AMC with each pregnancy. Because the severity of phenotype can vary even within a family that displays clear mendelian inheritance, predicting the visual potential of a second affected child is even more difficult.

A major concern for parents of a newborn with AMC is visual potential. Patients with unilateral visual loss adapt and generally require little in the way of visual aids, save for protective eyewear. Patients with bilateral abnormalities are more difficult to predict. In the setting of anophthalmia and extreme microphthalmia, we generally give a guarded visual prognosis. When uveal coloboma involves only the iris and/or the peripheral retina, vision is usually normal or near-normal. These children must still be followed regularly by a pediatric ophthalmologist as they are likely at risk for amblyopia due to astigmatism. Even in children with colobomas involving the optic nerve and/or macula, vision—although usually not 20/20—can be quite good. For this reason, we recommend careful, regular follow-up with a pediatric ophthalmologist, and have a low threshold for initiating spectacle correction and/or amblyopia treatment.

Molecular testing in AMC is also complicated. In the absence of other systemic findings and/or a defined syndrome, the yield of sequencing known genes remains low (3,94). Raca et al. report that clinically interpretable abnormalities on array comparative genomic hybridization is low in isolated AMC (149). As such, there is no single “high-yield” molecular test for nonsyndromic AMC at present, and clinical judgment tempered with the cost-benefit for the individual patient remains the guiding principle.

### 141.5 PERSISTENCE OF THE FETAL VASCULATURE/PERSISTENT HYPERPLASTIC PRIMARY VITREOUS

PFV—also known as persistent hyperplastic primary vitreous (PHPV)—is most often a sporadic unilateral congenital ocular malformation (150). During normal embryogenesis, periocular mesenchyme invades the center of the OC via the open OF. As the OF closes, this mesenchyme organizes to form the fetal vasculature of the developing eye. This hyaloid vasculature runs distal from its origin in the optic stalk, through the primary vitreous cavity, and encircles the developing lens. At the time of full-term birth, this primordial circulation has largely regressed, leaving the lens and vitreous cavity avascular. In PFV, the remnants of the hyaloid vasculature fail to completely regress. Often, PFV is associated with microphthalmia and a dense fibrotic plaque on the posterior surface of the lens. Adhesions between the iris and the anterior lens, glaucoma, and dragging of the ciliary body are also sometimes observed. Visual prognosis is usually guarded. While most PFV is sporadic, AR

**FIGURE 141-5** Uveal coloboma may be asymptomatic and undetectable without a detailed, dilated fundoscopic examination. Such “microforms” of coloboma as this focal RPE abnormality—when seen in the parent of a child with coloboma—help establish a pattern of inheritance and assist in genetic counseling.

(OMIM %611311) (151) and AD (OMIM %611308) (152) inheritance have been reported.

## Biography

**Brian P Brooks** obtained his MD and PhD from the University of Pennsylvania. His residency training in ophthalmology and fellowship training in pediatric ophthalmology were completed at the University of Michigan. Dr Brooks completed a clinical genetics fellowship at the Metropolitan Washington DC Medical Genetics program centered at the National Human Genome Research Institute. Dr Brooks is one of the few physicians in the United States boarded in both ophthalmology and clinical genetics. He is currently Chief, Unit on Pediatric, Developmental, and Genetic Ophthalmology in the Ophthalmic Genetics and Visual Function Branch of the National Eye Institute. In 2010, he was awarded the Presidential Early Career Award for Science and Engineering by President Barak Obama, the nation's highest honor for young investigators.

**GLOSSARY**

**Aminoglycoside** – antibiotic used to treat Gram negative bacterial infection  
**Auditory neuropathy** – SNHI in which ABRs are absent or severely distorted but OAEs are present  
**Cochlea** – part of ear with sensory apparatus  
**Congenital** – present since birth  
**Eustachian tube** – connection between throat and middle ear  
**Hemosiderin** – breakdown byproduct of hemoglobin  
**Neural transmitter** – chemical involved in signal transduction at nerve endings  
**Otoacoustic emissions** – sounds produced in the cochlea by the mechanical activity of outer hair cells  
**Ototoxic** – damaging to the ear  
**Pathogenesis** – medical explanation for a particular finding  
**Penetrance** – likelihood that individuals with an abnormal gene will manifest the expected condition  
**Pinna** – external part of the ear  
**Retrocochlear** – auditory pathway from the cochlea to the brain, not involving the cochlea  
**Teratogen** – agent that causes damage to developing fetus when used during pregnancy  
**Syndrome** – recognizable pattern of findings reflecting a common pathogenesis  
**Vestibule** – part of ear with balance apparatus

**ABBREVIATIONS**

**ABR** – auditory brainstem response  
**ADNSHL or ADNSHI** – autosomal dominant non-syndromic hearing loss/impairment  
**ARNSHL or ARSNHI** – autosomal recessive non-syndromic hearing loss/impairment  
**AEP** – auditory evoked potentials  
**ARHI** – age-related hearing impairment (presbycusis)  
**AUNA/AUNB** – AD or AR auditory neuropathy  
**DFN** – deafness

**DFNA** – autosomal dominant non-syndromic hearing loss loci  
**DFNB** – autosomal recessive non-syndromic hearing loss loci  
**DFNX** – X-linked non-syndromic hearing loss  
**HI/HL** – hearing impairment/hearing loss  
**NSHL/NSHI** – non-syndromal hearing loss/impairment  
**OAE** – otoacoustic emissions  
**SNHL** – sensorineural hearing loss

**142.1 INTRODUCTION**

Hearing loss (HL) is the most common sensory abnormality in humans. In view of the complexity of the hearing mechanism, it is not surprising that HL can result from a wide variety of genetically determined aberrations, which involve virtually every type of biological function. These changes may be specific to hearing (non-syndromic) or can affect additional organs (syndromic), and sometimes require additional environmental triggers for phenotypic expression. We will discuss the normal anatomy and physiology of the hearing apparatus briefly, as well as the prevalence and classification of hereditary deafness. The embryology of the ear, although relevant to a full understanding of some of the developmental cases of syndromic deafness, is beyond the scope of this chapter. The clinical features associated with non-syndromic and syndromic HL, as well as the differential diagnosis, evaluation, and management of an individual with HL is described from a clinical genetics perspective. Recent advances in newborn hearing screening, as well as some of the problems, challenges, and culture of the deaf individual and community will be addressed. Throughout the chapter, current knowledge regarding the presentation, pathophysiology, and molecular aspects of hereditary HL will be summarized. Many genes involved in hereditary HL have been cloned, and the chromosomal locations

of many additional ‘deafness’ genes have been identified. Many of these findings have implications for clinical management and counseling, particularly in the diagnosis of autosomal recessive or X-linked nonsyndromic HL, in the prevention of aminoglycoside-induced ototoxicity in genetically susceptible individuals, and in the implementation of universal newborn hearing screening.

## 142.2 ANATOMY AND PHYSIOLOGY

The ear is divided into external, middle, and inner sections. The external part consists of the pinna and auditory canal, which ends in the tympanic membrane. The tympanic membrane represents the barrier between the external and middle ear. The middle ear is air filled; contains three bones, the malleus, incus, and stapes; and is linked to the oropharynx through the eustachian tube. The middle ear connects to the inner ear at the membranes of the oval and round windows. The inner ear contains the fluid-filled cochlear and vestibular systems, in which the receptors for hearing and equilibrium, the hair cells, are located. The cochlea is formed by the membranous cochlear duct, an elongated tube with  $2\frac{1}{2}$  turns containing the organ of Corti, the scala vestibuli, and the scala tympani, which surround the cochlear duct and connect at its apex.

Hearing occurs when sound reaches the tympanic membrane through the external acoustic meatus, vibrations are transmitted and amplified through the three middle ear bones, and the movement of the footplate of the stapes produces vibration of the oval window membrane. This causes pressure changes at the base of the scala vestibuli. The pressure wave travels first to the apex of the scala vestibuli, connects to the scala tympani, and the energy is then dissipated at the round window. The basilar membrane in the scala tympani vibrates as well, and presses the filaments of the hair cells of the organ of Corti against the tectorial membranes. This deflection of the stereocilia of the outer hair cells (OHC) begins the process of membrane depolarization, which transmits the acoustic signal to the inner hair cells, ultimately leading to auditory nerve activation via the cells of the spiral ganglion. The basal portion of the basilar membrane is maximally responsive to high-frequency sounds, while the apical portion is most sensitive to low-frequency sounds. Activation of the hair cells leads to release of neurotransmitters from the basal part of the hair cells, and activation of the afferent axon of the cochlear nerve. A short introduction to the extraordinary physiology of the 32,000 human cochlear hair cells, and their ability to transmit, by mechanical means, precise information about events taking place in microseconds, can be found in reviews by Hudspeth (1) and by Dror and Avraham (2). The cell bodies of the cochlear nerve are located in the petrous part of the temporal bone, with the afferent axons reaching to the hair cells, while the efferent ones enter the pons and split to go to the ventral and dorsal cochlear nuclei. At least two neurons are required

from here through the superior olive, lateral lemniscus nucleus, and inferior colliculus to the medial geniculate body in the midbrain (many but not all of the fibers cross to the contralateral side, mostly at the level of the pons). From there, the acoustic radiation extends to Heschl’s gyrus in the temporal lobe, where there is a point-to-point correspondence with the cochlea (low frequency to high frequency).

## 142.3 PREVALENCE AND CLASSIFICATION OF HL

### 142.3.1 Prevalence

HL is the most common neurosensory deficit, affecting around 270 million people worldwide. There are at least 36 million deaf and hearing-impaired people in the United States, 2 million of whom have severe-to-profound deafness (3). About 40–50% of individuals aged 65 and above have some degree of age-related hearing impairment (ARHI). Recent evidence suggests that ARHI (presbycusis) occurs due to a combination of environmental and hereditary factors (4,5), and variants in several genes, including the sodium acetyltransferase 2 gene (6), *GRM7*, encoding metabotropic glutamate receptor type 7 (7), and *GRHL2* (see DFNA28) (8) have been implicated in the process of age-related hearing loss (AR HL). Our discussion focuses on hereditary HI of childhood, which comprises most of the severe forms of inherited deafness, and includes examples of several common disorders associated with genetic hearing impairment in adults. It is estimated that 3 per 1000 children under the age of 3 years, and 4 per 1000 children under the age of 19 years, are hearing impaired. HL can be classified according to several parameters, each of which has important implications for diagnosis, prognosis, and therapy, as discussed in the later sections of this chapter.

### 142.3.2 Severity

The ‘loudness’ of a sound is described by the decibel (db), which is the logarithm to the base 10 of the intensity of the sound wave relative to a reference intensity, divided by 10. Most conversational speech occurs at 45–60 db. The severity of the HL is frequently divided into the following categories:

Mild	26–40 dB
Moderate	41–55 dB
Moderately severe	56–70 dB
Severe	71–90 dB
Profound	90+ dB

### 142.3.3 Anatomy/Physiology

The two major subgroups in this classification are conductive and sensorineural HL. In conductive deafness,

the defect resides in the external or middle ear, while in sensorineural deafness (also called perceptive or neural deafness), the abnormality lies somewhere between the hair cells of the cochlea and the auditory regions of the brain. SNHL is frequently subdivided into cochlear and retrocochlear deafness, depending on the localization of the defect. Mixed deafness includes both conductive and sensorineural components.

### 142.3.4 Associated Features

Deafness associated with abnormalities in other organ systems is called syndromic deafness, while deafness not associated with other abnormalities is classified as non-syndromic in nature.

**Time of onset:** If deafness is present at birth or during early infancy, it is considered congenital, and is frequently associated with an inability to acquire normal speech. Hearing impairment occurring subsequently is called either early-onset or late-onset HL, but no clear age brackets differentiate these types.

### 142.3.5 Etiological and Molecular Classification

Hearing impairment may be due to genetic or environmental causes. As described in the following sections, mutations in an ever-growing number of genes have been associated with nonsyndromic and syndromic HL. Molecular data will be used increasingly to define the nature of the hearing impairment, and, in some cases, to suggest anticipatory care strategies. When classifying childhood deafness using some of the criteria outlined here (Table 142-1), the proportion of affected individuals in each group varies among different studies. Although some variation may be related to ethnic and environmental differences, the manner in which patients were selected and the extent of their diagnostic evaluation influence the data. Many patients with apparently idiopathic deafness will eventually be classified more

specifically. Thus any etiological classification should be used only as a general guideline.

In addition to the previously noted difficulties in classifying HL patients, the following features may also distort the true percentages:

- Cases of acquired HL may occur in individuals who have a genetic predisposition to be adversely affected by an environmental factor.
- It is frequently difficult to differentiate between isolated HL due to a genetic defect and that due to an environmental cause, such as prenatal insult e.g. congenital CMV infection, or exposure to certain medications. Also, there is a tendency for parents and well-meaning physicians to attribute HI to some non-genetic cause. On the other hand, a causative insult may have been forgotten or unrecognized.
- Autosomal recessive nonsyndromic deafness may be overestimated, since autosomal dominant deafness with incomplete penetrance, or requiring interaction with environmental factors, might mimic a recessive trait in which both parents appear to be unaffected. Similarly, simplex ADSNHL cases may be misclassified as sporadic due to the lack of affected family members.
- Syndromic deafness may be underestimated, since the syndromic expression might be so mild as to be overlooked, or the syndromic component may develop only at a later time.

Lastly, it should be noted that many cases of congenital deafness are acquired, while many late-onset cases of deafness are genetic or reflect a genetic predisposition to an environmental factor.

## 142.4 ACQUIRED HEARING IMPAIRMENT

HL may be acquired through a variety of physical, chemical and infectious mechanisms. Genetics plays a role both in the occurrence and presentation of these factors, and, sometimes, in the susceptibility of the patient to the agent. Acquired HL may be caused by meningitis, mastoiditis or chronic otitis media, trauma and noise abuse, kernicterus, myxedema and exposure to various pharmaceutical agents (including aminoglycoside antibiotics, quinine, loop diuretics and cis-platinum) and teratogens. Kernicterus, which is mainly due to Rh and ABO blood group incompatibility, and hypothyroidism often have a genetic etiology. A provocative study in mice (9) documented an effect on cochlear development in mice deficient in type 2 iodothyronine deiodinase (D2). The authors suggested complex interaction of the thyroid hormones, D2, and thyroid hormone receptors in the development, onset, and regulation of auditory function. Aminoglycoside ototoxicity demonstrates genetic susceptibility in a significant proportion of cases, as discussed later in the

**TABLE 142-1** Proportion of Deafness by Etiologic Classification

I. Genetic: 35% <sup>a</sup>
1. Nonsyndromic: 60%
a. Autosomal recessive: 70–80%
b. Autosomal dominant: 20–30%
c. X-linked: 1%
d. Mitochondrial, multilocus: <1%
2. Syndromic: 40%
II. Acquired: 35%
1. Prenatal: 20%
2. Perinatal: 20%
3. Later onset: 60%
III. Idiopathic: 30%

<sup>a</sup>Genetic etiology accounts for 50% of prelingual SNHL.

section on mitochondrial inheritance. An early study suggested that HL due to rubella embryopathy occurs predominately in the genetically susceptible fetus (10). Dodson and colleagues (11) proposed a common mechanism for some forms of acquired, late-onset, progressive SNHL in both nongenetic and genetic conditions. They noted that superficial siderosis, representing localized deposition of hemosiderin following recurrent subarachnoid bleeding, may be the cause of HL in patients with bleeding of nongenetic etiology as well as in syndromes such as Alport syndrome and related conditions, hereditary amyloidosis (transthyretin amyloidosis and Muckle-Wells syndrome), Marfan syndrome, neurofibromatosis type 1, and hereditary hemorrhagic telangiectasia. They comment that such a pathogenesis, if proven, would represent a manifestation of deafness caused by genes that are not expressed in the cochlea.

Toxicity associated with a large number of drugs, particularly salicylates, loop diuretics, aminoglycosides and various chemotherapeutic agents, has been associated with SNHL and will not be discussed here (see mitochondrial inheritance for review of aminoglycoside-induced HI in the setting of genetic susceptibility). In addition, a recent study of chronic analgesic use in men showed that acetaminophen and other NSAIDs were associated with an increased risk of SNHL, particularly in younger individuals (12). Sudden-onset HL has been described in patients with chronic hepatitis C treated with pegylated interferon and ribavirin (13,14), and after recreational use of Vicodin (15,16). Otosyphilis (acute luetic hydrops) may be associated with acute onset HL, particularly in the setting of HIV (17), and shows improvement if treatment is initiated promptly (18). Persistent, localized measles virus infection is a major cause of adult-onset HL and is discussed in the section on otosclerosis. SNHL occurs as a secondary phenomenon in long-standing diabetes mellitus, most likely on the basis of chronic microvascular insult and sensory neuropathy. Other environmental exposures, especially cigarette smoking, may play a role in ARHL (19). Notably, a recent study implicates second hand smoke as a cause of low-frequency HL in adolescents (20). In addition to its contribution to presbycusis, noise abuse, in the form of personal stereo usage, has been associated with slight-mild HL in children (21), and may be an early precursor to later, progressive SNHL. Finally, SNHL occurs as a secondary phenomenon in long-standing diabetes mellitus, most likely on the basis of chronic microvascular insult and sensory neuropathy.

### 142.5 TERATOGENIC HEARING IMPAIRMENT

The effects of a number of human teratogens, ranging from infectious agents to rarely used therapeutic modalities, play a significant role in HL. The classical example of an intrauterine viral agent with teratogenic effects on

the human fetus is the rubella virus. Although rubella infection was highly prevalent, with a pandemic occurring in the United States between 1962 and 1965, the widespread use of childhood rubella vaccination, initiated in 1969, has helped control the congenital transmission of this virus in most Western populations. Though congenital cataracts comprised the first reported association between maternal rubella virus and fetal abnormality, the importance of deafness was soon documented. Rubella embryopathy presents a striking pattern of features, including cataracts, congenital cardiovascular defects, microcephaly, and mental retardation, as well as SNHL, which is the most frequent finding. The likelihood of finding an abnormality is closely related to the gestational age at maternal infection, and, although the likelihood of full-blown rubella embryopathy is quite low after 16 weeks, infection at any time in pregnancy may result in hearing impairment.

Congenital cytomegalovirus (CMV) infection, which has long been associated with HL, even in the case of inapparent infection, is now the leading cause of late-onset childhood HL (22,23). It is estimated that of the 20,000–40,000 infants born each year with congenital CMV infection in the United States, 90% have no detectable clinical abnormalities at birth and will not be detected by a clinical examination. Ear anatomy is usually normal, though a Mondini defect may be present occasionally. SNHL occurs in 10–15% of these asymptomatic infants, may present in early childhood and can be unilateral or bilateral. Since CMV-associated HL is often later onset and progressive, affected children may be missed by newborn hearing screening (24). Several studies document detection of CMV DNA using polymerase chain reaction in both Guthrie blood spots (25) and perilymph (26,27). A recent report of PCR-based evaluation of saliva suggested a strategy for targeted newborn screening for CMV (28). These techniques may be particularly important in light of evidence that early ganciclovir treatment of symptomatic children may prevent HL (29–31). The association of SNHL and congenital toxoplasmosis has been reviewed recently (32).

While its importance is muted by the other neurological sequelae, SNHL also occurs as part of the spectrum of untreated congenital syphilis, though it is unlikely to occur in children who are diagnosed at birth and treated appropriately (33).

Fetal alcohol syndrome is characterized by growth failure, microcephaly, typical facies, congenital heart defects, subtle skeletal anomalies, and variable mental retardation. Pinna anomalies and serous otitis media occur frequently, with consequent conductive HL adding to the developmental burden (reviewed by Mulvihill (34)). In a study of affected children referred for ear, nose, and throat evaluation, 4 of 14 demonstrated significant bilateral SNHL (35), suggesting a developmental effect of the inner ear. Though this observation was not

confirmed in a larger study (36), the authors emphasized the importance of early recognition and treatment for HI in children with FASD. Thalidomide has been associated with conductive HL secondary to hypoplasia or atresia of the external acoustic meatus, ossicular fusion or other defects, and inner ear anomalies (37–39). Of note, some cases previously attributed to thalidomide embryopathy represent the spectrum of SALL4-related disorders described later (40). Retinoic acid embryopathy also includes conductive HL secondary to microtia and malformation of the auditory canal (41), as does exposure to mycophenolate mofetil, which may result in craniofacial features overlapping those of Treacher-Collins syndrome or bilateral hemifacial microsomia but is also associated with major cardiac defects (42). Other human teratogens associated with HL include quinine, which induces inner ear abnormalities in rodents, trimethadione, fetal iodine deficiency, and fetal methyl mercury effects.

## 142.6 NONSYNDROMIC HEREDITARY HEARING IMPAIRMENT

About 70% of inherited deafness is not associated with any symptoms or signs apart from the HL, and is called nonsyndromic HL. This has been classified according to the pattern of inheritance into autosomal recessive (DFNB nomenclature assignment), autosomal dominant (DFNA), X-linked (DFNX), mitochondrial (maternal), and modifying loci (DFNM). While not clearly established, there is one report of purportedly Y-linked hearing impairment segregating in a large Chinese kindred (43). There is great clinical and genetic heterogeneity within each of the major categories. Clinical subdivision of each group according to age of onset, severity, and audiometric abnormalities has been attempted, but allows only a very general subclassification. The recent advances in molecular genetics have led to the identification of more than 127 chromosomal regions involved in nonsyndromic HL. At least 69 auditory genes have been identified – 24 autosomal dominant (AD), 40 autosomal recessive (AR), 2 X-linked, and 3 mitochondrial – in addition to a large number of genes for syndromic HL. This allows for a more precise classification of nonsyndromic deafness, for early diagnostic testing and intervention in some cases, and, rarely, for implementation of preventive measures. It should be noted that documentation of the genetic abnormality does not necessarily allow accurate prediction of the clinical phenotype. In addition, mutations in the same gene are known to cause both nonsyndromic and syndromic HL, can cause both AR HL and AD HL, or can cause more severe HI in some patients than in family members who carry the same mutation. Also, from a clinical perspective, it is important to stress the possibility that the initial diagnosis of nonsyndromic deafness may be revised if other symptoms appear later in life, as may occur, for example, in Pendred syndrome and Usher syndrome.

### 142.6.1 Autosomal Recessive Hearing Impairment

AR inheritance accounts for 75–80% of all cases of non-syndromic prelingual deafness (44). Most children with AR HI have congenital HI, are born to hearing parents, and seldom have a history of environmental exposure. Hearing impairment is always sensorineural, and severe, moderate, and early-onset varieties have been described. In general, AR HI is more severe than ADSNHL, and is typically nonprogressive. One of the earliest observations about AR deafness was its striking genetic heterogeneity, since the offspring of two unrelated partners with AR deafness usually have normal hearing. Recently, this concept has been substantiated with molecular tools. Thus far more than 50 different chromosomal regions have been found to contain genes leading to AR HL (45). These AR loci are denoted DFNB and are numbered in order of identification. For 40 of these regions, the genes responsible for the HL have been identified. To date, only 5 genes, *MYO3A* (DFNB30), *PJVK* (DFNB59), *LOXHD1* (DFNB77), and, occasionally, *TMPRSS3* (DFNB8/10) and *GJB2* (DFNB1), have been associated with progressive AR hearing impairment.

Because of its unexpectedly high contribution to non-syndromic hereditary HL, the most important gene is gap junction protein beta-2 (*GJB2*), which codes for the connexin (Cx) 26 protein:

- *GJB2* mutations account for approximately 50% of ARSNHI (DFNB1) and some cases of ADSNHI (DFNA3)
- *GJB2* mutation is the most common genetic cause of prelingual SNHL
- 35delG (a deletion of one in a string of six guanine nucleotides) comprises 70% of mutant alleles in ethnically diverse DFNB1 kindreds and represents a deletion hot spot (46)
- 35delG accounts for 80% of DFNB1 in Mediterraneans (47)
- *GJB2* mutations are found in 10% of ‘sporadic’ cases of nonsyndromic SNHI (48)
- The 35delG carrier rate is approximately 1 in 40 in the western hemisphere
- The 167delT mutation is common in Ashkenazi Jews with a carrier rate of 1 in 25 (49)
- The 235delC mutation occurs commonly in Asian populations

Mutations in *GJB2* are responsible for DFNB1, and account for half of all autosomal recessive deafness cases in various populations (49–51). *GJB2*-related HL is typically bilateral and nonprogressive, though progression has been noted. In over 80% of cases, the HI falls into the severe-profound range. Since the gene is very small, consisting of a single coding exon, and since two specific mutations, 35delG and 167delT, account for a significant proportion of the affected alleles in many populations,

effective screening for *GJB2* mutation is feasible. Due to the high prevalence of the 167delT mutation among Ashkenazi Jews, carrier screening has been suggested for this population. Mutations in *GJB2* make a smaller contribution to prelingual deafness in other populations and the mutation spectrum is different, with the 235delC mutation playing a prominent role in Asian populations (52–54). The genetic epidemiology, prevalence rates, and genotype–phenotype correlation of *GJB2* alleles were reviewed by Kenneson and colleagues (51). Genotype–phenotype correlations have also been described by Azaiez and coworkers (54), who suggested that at least one noncompensating mutation outside the coding region of *GJB2* contributes to HL associated with the DFNB1 locus. SNHL at the DFNB1 locus also may be caused by digenic interaction of a *GJB2* mutation and a deletion of *GJB6* (connexin 30). As described by del Castillo and colleagues (55), this 309-kb deletion is the second most common mutation found in nonsyndromic prelingual deafness in the Spanish population. This observation has been confirmed in other populations (56,57). The KID syndrome of keratitis, ichthyosiform erythroderma, deafness, and other findings is associated with progressive neovascularization of the cornea and of corneal grafts such that deafness-blindness may occur. KID syndrome has been associated with some mutations in *GJB2*, (58), providing a striking example of syndromic and nonsyndromic HL resulting from mutations in the same gene. Because a recurrent mutation (D50N) in *GJB2* is observed in Japanese patients with nonsyndromic HL (59) and in Austrian KID syndrome patients, Janecke and colleagues (60) suggested that the phenotype caused by this mutation depended on the genetic background of the affected individual.

DFNB2 and DFNB3 (see Table 142-2) are caused by mutations in the genes that encode the unconventional myosins 7A (61,62) and 15 (63), respectively. These myosins interact with actin in the hair cells of the inner ear, and affect stereocilia organization and hair cell contractility (see Usher syndrome). Myosin 7A is also associated with ADSNHL (64). DFNB4 is caused by mutations in a chloride-iodide-bicarbonate transporter (65,66) called *SLCA4*, which encodes pendrin (discussed in the section on Pendred syndrome). DFNB6 is caused by loss of function mutations in a novel gene, *TMIE*, which result in severe-to-profound prelingual deafness (67). Studies in Turkish families identified a founder mutation responsible for about 3% of ARSNHL in Turkish families and about 12% in families from southern Turkey (68). DFNB7 and DFNB11 are caused by mutations in a novel gene, *TMC1* (transmembrane cochlear expressed gene 1), which is required for physiological hair cell function (69). DFNB8 and DFNB10 are caused by mutations in a type II transmembrane serine protease [*TMPRSS3*], the first description of a protease involved in HL, manifesting both congenital HL (DFNB10) and childhood-onset, progressive HL (DFNB8) (70). *TMPRSS3* regulates the activity of an

epidermal sodium channel, ENaC, suggesting that it is an important regulator of sodium concentration in the cochlea (71).

DFNB9 is caused by mutations in *OTOF*, the gene encoding otoferlin (72), a protein involved in trafficking (exocytosis) synaptic vesicles of inner hair cells (73), which works in concert with myosin VI (DFNB37/A22) and is the proposed calcium sensor during inner hair cell exocytosis (74). A founder mutation in *OTOF*, Q829X, is responsible for 4–5% of sporadic and AR cases of non-syndromic SNHL in the Spanish population (75). HI associated with *OTOF* mutations is generally congenital and may present as an auditory neuropathy (see below) with early preservation and later loss of evoked otoacoustic emissions (OAE), raising a concern that neonatal screening utilizing transient evoked OAEs will miss such children (76). *OTOF* is also associated with later-onset HL at the first AR auditory neuropathy locus, AUNB1 (see below). DFNB12 is caused by an allelic mutation of the novel cadherin-like gene *CDH23* (77), which is also the gene implicated in Usher syndrome at the USH1D locus (see below). Mutations in *GIPC3*, which encodes the GAIP C-terminus-interacting protein 3, one of a protein family which interacts with a variety of other proteins involved in signal transduction, vesicular trafficking, endocytosis and neurotransmitter release, are responsible for HL at the DFNB15/72/95 loci (78,79). Mouse and human studies suggest that normal function of this gene, which is highly expressed in the inner hair cells and spiral ganglion, appears to be critical for the acquisition and propagation of acoustic signals. DFNB16 is caused by mutations in *STRC*, encoding a stereocillin expressed only in the sensory hair cells, and is associated with the stereocilia, the stiff microvilli forming the structure for mechanoreception of sound stimulation (80).

DFNB18 is caused by mutations in the alternatively spliced exons of *USH1C*, which is also a cause of Usher syndrome (81,82). DFNB21 is associated with mutations in the gene *TECTA*, encoding a protein constituent of the tectorial membrane,  $\alpha$ -tectorin, which is in contact with the sensory hair cells via the stereocilia (83). DFNB22, caused by mutations in the gene *OTOA*, which encodes the protein otoancorin, is involved in the attachment of the inner ear acellular gels to the apical surface of the underlying nonsensory cells (84). DFNB23 is caused by missense mutations of *PCDH15*, which encodes the protein protocadherin 15. This protein localizes to inner ear hair cell stereocilia and plays a role in the morphogenesis and cohesion of stereocilia bundles of the inner ear (85). Nonsense mutations in *PCDH15* are associated with another Usher syndrome locus, USH1F. Mutations in *RDX*, which encodes radixin, an ezrin-moesin-like protein critical for anchoring actin to sensory hair cell membranes, are associated with HL at the DFNB24 locus (86). Congenital severe-profound SNHL, sometimes associated with vestibular dysfunction is caused by mutations in

**TABLE 142-2 Autosomal Recessive (DFNB) Deafness Genes**

Locus	Gene	Protein/Function
DFNB1	<i>GJB2</i> <sup>a</sup>	Connexin 26; gap junction protein, major gene associated with prelingual ARSNHL
DFNB2 (DFNA11) (USH1B)	<i>MYO7A</i>	Myosin VIIA; stereocilia organization, hair cell contractility, transmembrane protein transport
DFNB3	<i>MYO15</i>	Myosin XV; interacts with actin and myosin VIIA
DFNB4	<i>SLC4A</i>	Pendrin; chloride-iodide-bicarbonate transporter
DFNB6	<i>TMIE</i>	Novel transmembrane inner ear expressed gene; needed for sensory hair cell development/maturation
DFNB7/11 (DFNA36)	<i>TMC1</i>	Transmembrane channel-like protein1; required for normal hair cell function
DFNB10	<i>TMPRSS3</i> <sup>b</sup>	Transmembrane serine protease 3, sodium regulator
DFNB9 (AUNB1)	<i>OTOF</i>	Otoferlin; synaptic vesicle trafficking, may present with auditory neuropathy
DFNB12 (USH1D)	<i>CDH23</i>	Cadherin 23; interacts with myosin VIIA and harmonin in USH supercomplex
DFNB15/72/95	<i>GIPC3</i>	GAIP PDZ domain protein 3; critical for IHC/OHC and spiral ganglion maintenance, signal transduction
DFNB16	<i>STRC</i>	Stereocillin; stiffens hair cell microvilli to assist in mechanoreception of sound
DFNB18 (USH1C)	<i>USH1C</i>	Harmonin; associates with a scaffold-like protein encoded by SANS, and all USH proteins
DFNB21 (DFNA8/12)	<i>TECTA</i>	$\alpha$ -Tectorin; tectorial membrane element
DFNB22	<i>OTOA</i>	Otoancorin; acellular gel component
DFNB23 (USH1F)	<i>PCDH15</i>	Protocadherin 15; morphogenesis and adhesion of stereocilia bundles, interacts with USH proteins
DFNB24	<i>RDX</i>	Radixin; anchors actin to sensory hair cell membrane
DFNB25	<i>GRXCR1</i>	Glutaredoxin, cysteine-rich 1; predicted protein modification via reversible protein S-glutathionylation
DFNB28	<i>TRIOBP</i>	TRIO and F-actin binding protein; needed for actin/stereocilia rigidity and flexible stereocilia rootlets
DFNB29	<i>CLDN14</i>	Tight junction claudin-14; structural support of auditory neuroepithelium in the organ of Corti
DFNB30	<i>MYO3A</i> <sup>a</sup>	Myosin IIIA; unconventional myosin, motor protein
DFNB31 (USH 2D)	<i>WHRN</i>	Whirlin; stereocilia elongation, critical USH protein, interacts with harmonin and SANS
DFNB35	<i>ESRRB</i>	Estrogen receptor-related receptor B; role in cochlear development and maintenance
DFNB36	<i>ESPN</i>	Espin; calcium-insensitive actin binding
DFNB37 (DFNA22)	<i>MYO6</i>	Myosin VI; unconventional myosin with multiple cellular functions
DFNB39	<i>HGF</i>	Hepatocyte growth factor; hair cell integrity
DFNB42	<i>ILDR1</i>	Insulin-like domain-containing receptor 1; unknown
DFNB49	<i>MARVELD2</i>	Tricellulin; tight junction protein critical for epithelial barrier maintenance in inner ear compartments
DFNB53 (DFNA13)	<i>COL11A2</i>	Type XI, alpha 2 collagen; fibrillar extracellular matrix component, tectorial membrane fibrils
DFNB59	<i>PJVK</i> <sup>a</sup>	Pejvak; Gasdermin family member, homology to DFNA5, cochlear hair cell and neuronal function
DFNB61	<i>SLC26A5</i>	Prestin; solute load carrier family, cochlear outer hair cell elongation, regulated by thyroid hormones
DFNB63	<i>LRTOMT</i>	Catecholamine-O-methyltransferase (COMT2); High cochlear expression, exact role unknown
DFNB67	<i>LHFPL5</i>	LHFP-like protein 5; transmembrane protein localized to mouse inner and outer hair cell stereocilia, function unknown
DFNB73	<i>BSND</i>	Barttin; Bartter syndrome gene, regulates potassium potassium recycling via chloride channel
DFNB74	<i>MSRB3</i>	Methionine sulfoxide reductase; recycles oxidized proteins, LOF may cause apoptosis
DFNB77	<i>LOXHD1</i> <sup>a</sup>	Lipoxygenase homology domain-containing 1 protein; highly conserved stereociliary protein
DFNB79	<i>TPRN</i>	Taperin; multiple functions, modulates actin dynamics
DFNB82	<i>GPSM2</i>	G-protein signaling modulator; maintains cell polarity
DFNB84	<i>PTPRQ</i>	Protein tyrosine phosphatase receptor Q; Interacts with myosin 6, stabilizes stereociliary actin ankle links
DFNB91	<i>SERPINB6</i>	Encodes a SERPIN peptidase inhibitor; may protect against stress-induced lysosomal leakage

<sup>a</sup>These genes may present with progressive hearing loss.

<sup>b</sup>DFNB8 onset is at age 8–10 with rapid progression; DFNB10 onset is congenital, stable.

*GRXCR1* at the DFNB25 locus (87). The glutaredoxin (GLX) domain is predicted to function in protein modification through the process of reversible S-glutathionylation, which affects protein localization and activity. This highly conserved gene is expressed primarily in embryonic cochlea. Pirouette (pi) mouse strains with spontaneous *Grxcr1* mutations have thin, foreshortened sensory hair cell stereocilia (88). *TRIOBP*, which encodes a filamentous actin-binding protein, is associated with HL at the DFNB28 locus (89,90). Kitahiri and co-authors (91) noted that deafness-causing mutations are located in exon 6 of *TRIOBP* and affect two of the three alternatively spliced forms of the protein,

*TRIOBP4* and *TRIOBP5*. They also described a mouse model, which demonstrated that normal *TRIOBP* promotes dense bundling of actin filaments, which allows mechanical rigidity of the stereocilia and ‘durable flexibility’ at the tapered end of actin. DFNB29 is caused by mutations in the gene encoding tight junction claudin-14 (*CLDN14*), which localizes to the sensory epithelium of the organ of Corti and likely provides structural support for the auditory neuroepithelium (92). DFNB30 is caused by mutations in *MYO3A*, encoding the unconventional myosin IIIA (93), another molecular motor protein, and one of the genes associated with progressive ARSNHL. DFNB31 results from

mutations in the gene *WHRN*, which encodes the scaffold protein whirlin, a PDZ domain molecule involved in stereocilia elongation (94), which also causes Usher syndrome, type 2D (95).

DFNB35 is caused by mutations in *ESRRB* (96), which encodes an estrogen-related receptor. Normal *ESRRB* expression appears to be important in both cochlear development and postnatal function. DFNB36 is caused by mutations in the gene *ESPN*, which encodes a calcium-insensitive actin-binding protein, espin, and presents as deafness with vestibular dysfunction and areflexia (97). DFNB37 is due to mutations in *MYO6*, which encodes the unconventional myosin VI protein. *MYO6* is involved in many processes in the inner ear, including membrane trafficking, recycling, cell movement and endocytosis (98), and has been proposed to interact with otoferlin (DFNB9) in the recycling of inner hair cell synaptic vesicles (74). Schultz and colleagues showed that mutations in *HGF*, a potent mitogen whose multiple isoforms are widely expressed in embryonic and adult tissues, result in profound, prelingual SNHL at the DFNB39 locus (99). They developed a conditional mouse *Hgf* knockout model which showed multiple cochlear anomalies including disorganization of the tectorial membrane, thin, flat stria vascularis, hypoplastic spiral ganglion and a graded pattern of outer hair cell degeneration ranging from complete loss of basilar OHC to milder involvement of apical cells. DFNB42 is caused by mutations in the insulin-like domain-containing receptor 1 gene, *ILDR1*, which encodes a transmembrane receptor of unknown function expressed in the vestibule and in cochlear hair cells and supporting cells during mouse embryogenesis (100).

Affected individuals carry truncating mutations, suggesting that the severe-profound, bilateral, prelingual SNHL is due to loss of function of the gene. Deafness at the DFNB49 locus results from mutations in *TRIC* (renamed *MARVELD2*, for MARVEL domain-containing protein 2), which encodes tricellulin, a tight-junction protein widely expressed in epithelia (101). Tricellulin appears to be an integral element in maintaining the structure and function of epithelial barriers in the various compartments of the inner ear. Some mutations in *COL11A2* (see DFNA13 and Stickler syndrome) result in AR SNHL at the DFNB53 locus (102). Molecular studies implicated *PJVK*, which encodes pejavakin, a member of the same family of highly conserved vertebrate proteins as DFNA5, in auditory neuropathy associated with the DFNB59 locus (103). DFNB59 is the first example of a human gene involved in neuronal HL. Missense mutations are associated with a cochlear phenotype, while nonsense mutations result in progressive SNHL as well as vestibular dysfunction (104). A motor protein, prestin, which is expressed dramatically in the cochlear outer hair cells, has been implicated as the cause of nonsyndromic SNHL in several families (DFNB61). The prestin gene is a member of the solute load carrier

superfamily (specifically, *SLC26A5*) and mitigates rapid elongation of the outer hair cells (105). Prestin expression is regulated by thyroid hormones, suggesting that HL associated with hypothyroidism may be mediated by inadequate prestin function (106).

DFNB63 results from mutations in the gene *LRTOMT*, a leucine-rich transmembrane O-methyltransferase (catecholamine-O-methyltransferase 2 or COMT2), which is highly expressed in the cochlear and vestibular hair cells, implicating catecholamine catabolism in the pathogenesis of the hearing impairment (107,108). Mutations in the lipoma HMGIC fusion partner-like 5 (*LHFPL5*), gene, encoding a transmembrane protein, are associated with SNHL at the DFNB67 locus (109,110). Although its homology to tmhs, the gene responsible for the ‘hurry scurry’ mouse phenotype, suggests an important role in normal cochlear function (111), the exact role of this gene is not well understood. *BSND*, the gene which causes Bartter syndrome, is associated with HL at DFNB73 (112). Though classified as a form of nonsyndromic ARSNHL, some affected individuals may manifest mild symptoms of Bartter syndrome. *MSRB3* encodes a methionine sulfoxide reductase, important in restoring oxidized proteins to their functional form. Ahmed and colleagues (113) demonstrated that functional null mutations of *MSRB3*, which encodes a methionine sulfate reductase, are responsible for human deafness DFNB74, and postulated that abnormal or absent *MSRB3* activity might lead to unprogrammed caspase-activated apoptosis, which may be particularly damaging to the mitochondria of cochlear cells. Along with *TIMM8A*, the gene responsible for the deafness–dystonia–optic atrophy syndrome (Mohr–Tranebjaerg syndrome), *MSRB3* provides an example of a nuclear-encoded gene with critical mitochondrial function. Progressive SNHL at the DFNB77 locus is caused by mutations in *LOXHD1* (114). A mouse model of *LOXHD1* demonstrated expression along the membranes of mature hair cells, which were normally formed, but showed functional perturbation and eventual cell death. *TPRN*, encoding taperin, is associated with HL at the +DFNB79 locus. Taperin localizes to the stereocilia ankle links, and may have multiple functions in the vestibule and organ of Corti, including modulation of actin dynamics (115). Walsh et al. (116) found that mutations in the gene *GPSM2*, which encodes G-protein signaling modulator 2, a G-protein activator, is associated with HI at the DFNB82 locus. Mutations in *PTPRQ*, which encodes the protein tyrosine phosphatase receptor Q, cause congenital, progressive, moderate-profound SNHL and vestibular dysfunction at the DFNB84 locus (117). Evidence suggests that myosin 6 and PTPRQ protein interact to stabilize the stereocilia actin ankle-link attachment to the overlying membrane in cochlear and vestibular hair cells (118). HL at the DFNB91 locus results from mutations in *SERPINF6*, which encodes an intracellular protease inhibitor expressed in inner hair cells. Mutation results in absent protease function, which

may lead to stress-induced lysosomal ‘leakage’ with resultant hearing impairment (119). *GPSM2*, the gene responsible for HL at the *DFNB82* locus (116), shows widespread cochlear expression in a mouse model and is likely involved in determination of cell polarity.

### 142.6.2 Autosomal Dominant

AD inheritance accounts for approximately 20–25% of all cases of nonsyndromic childhood deafness (44). The following clinical subdivisions have been described: congenital severe-profound, progressive early onset, unilateral, low frequency, mid-frequency, and high-frequency progressive. As a rule, unilateral or mild bilateral HL and progressive HL are much more likely to occur on an AD rather than an AR basis. The HL is usually sensorineural, but conductive HL due to otosclerosis may present in childhood (see below). AD hearing loss (ADHL) also shows striking heterogeneity, though no single locus accounts for a significant proportion of cases, in contrast to the common *GJB2* (connexin 26) mutations responsible for the major portion of AR hearing loss. More than 50 different chromosomal regions identified so far contain genes leading to ADHL (45). The ADHL loci are designated DFNA and encompass loci from DFNA1 to DFNA60. DFNA8/12, DFNA 20/26, and DFNA6/14 are attributed to three common genes, *TECTA*, *ACTG1*, and *WFS1*, respectively. Two of the regions, DFNA2 and DFNA3, contain at least two genes that can cause ADHL. To date, 24 different genes have been identified as causing ADHL. Three of these, *GJB2*, *MYO7A*, and *TECTA*, have been described as causes of AR hearing loss. Two additional gap junction proteins, connexin 31 (*GJB3*) and connexin 30 (*GJB6*), have been found to cause some cases of HI at the DFNA2 and DFNA3 loci, respectively (120,121). Interestingly, DFNA2 can also be caused by a mutation in a gene encoding a novel potassium channel, *KCNQ4* (122) in cochlear outer hair cells, and DFNA3 can be caused by mutations in *GJB2*. Mutations in *KCNQ4* show a dominant-negative effect resulting in abnormal channel trafficking at the outer hair cell surface (123) (Table 142-3).

DFNA1 was the first ADSNHL locus, and was notable because of the presentation of low-frequency hearing loss (Konigsmark syndrome). HI is caused by mutations in *DIAPH1*, one of a family of genes involved in cell movement and cell polarity (124), which regulates actin polymerization and the interactions of the actin cytoskeleton with microtubules in the periphery of cochlear hair cells. *DIAPH1* is regulated by *MITF*, one of the genes involved in Waardenburg syndrome (WS) (125), suggesting a mechanism by which *MITF* mutations lead to HI in WS. DFNA4 is caused by mutations in the nonmuscle myosin heavy-chain gene, *MYH14* (126), encoding an ATP-dependent molecular motor protein which helps regulate cell motility, polarity and cytokinesis via its interactions with the actin cytoskeleton (127). Although

truncating mutations have been associated with HI at the DFNA5 locus for some time (128), the function of DFNA5 protein remained elusive, despite observations that the gene is frequently silenced in a variety of common tumors. Recently, Op de Beeck and colleagues (129) summarized prior data and presented an elegant series of studies demonstrating that DFNA5 promotes apoptosis in both the wild type and mutant states, and plays a role in cell survival. HI at the DFNA6/14/38 locus is caused by mutations in the Wolfram syndrome 1 gene (*WFS1*), and is a common cause of low frequency, slowly progressive, SNHL (130,131). DFNA8/14 is associated with the gene *TECTA*, which also causes ARSNHL at the DFNB21 locus.

A recent study in Spanish and American subjects (132) showed that *TECTA* mutations comprise a common form of ADSNHL and found that, in addition to mutations in the ZP domain, mutations in the N-terminal region of  $\alpha$ -tectorin are associated with mid-frequency HI. DFNA9, discovered using a tissue-specific approach to gene discovery in the auditory system, is caused by mutations in the novel cochlear gene *COCH*. Cochlin, the *COCH* gene product, shows homology to molecules involved in a variety of functions ranging from hemostasis to immune regulation to extracellular matrix assembly. Mutations in *COCH* cause progressive SNHL with vestibular pathology (133). DFNA10 is due to mutations in the activator gene *EYA4* and causes late-onset HI (134). DFNA11 is caused by mutations in the gene *MYO7A* (see DFNB2 and USH1B, which are also attributed to mutations in *MYO7A*). DFNA13, caused by mutations in the gene *COL11A2* (135), affects the triple-helix domain of the collagen protein, localizes to the tectorial membrane in *COL11A2* knockout mice, and causes mid-frequency SNHL. DFNA15 (at the 5q31 locus also assigned to DFNA54) is caused by mutations in *POU4F3*, which encodes a transcription factor (136). DFNA17 is due to mutations in *MYH9*, a nonmuscle myosin heavy-chain gene, and causes a phenotype of progressive HL and cochleasaccular degeneration (137), most likely because of a dominant-negative effect on myosin filament assembly (138), although the pathogenesis of the HI unclear. *MYR9* mutations are also associated with a spectrum of syndromic features including congenital thrombocytopenia with large platelets, white cell inclusions, high-frequency SNHL, presenile cataracts and glomerulonephritis (variously labeled Fechtner–Epstein syndrome, Sebastian syndrome, May–Hegglin anomaly) (139), which must be distinguished from Alport syndrome.

DFNA20/26 is caused by mutations in the cytoplasmic  $\gamma$ -actin gene, *ACTG1*, which represents the first gene to be associated with HL that can be attributed to cytoskeletal (nonmuscle) actin (140,141). Morin and colleagues (142) provided data indicating that mutations in *ACTG1* caused progressive HI due to hair cell

**TABLE 142-3 Autosomal Dominant (DFNA) Deafness Genes**

Locus	Gene	Protein/Function
DFNA1	<i>DIAPH1</i> <sup>a</sup>	Drosophila diaphanous protein 1 analog; role in cell polarity and movement; may regulate actin polymerization
DFNA2	<i>GJB3</i> <i>KCNQ4</i>	Connexin 31; gap junction constituent Potassium channel protein
DFNA3 (DFNB1)	<i>GJB2</i> <i>GJB6</i>	Connexin 26; gap junction constituent Connexin 30; gap junctions
DFNA4	<i>MYH14</i>	Nonmuscle myosin heavy chain 4
DFNA5	<i>DFNA5</i>	DFNA5; novel protein, homologous to Pejvakin, promotes normal and unscheduled apoptosis
DFNA6/14/38	<i>WFS1</i> <sup>a</sup>	Wolframin; integral transmembrane protein, also associated with Wolfram syndrome
DFNA8/12 (DFNB21)	<i>TECTA</i>	$\alpha$ -Tectorin; tectorial membrane element
DFNA9	<i>COCH</i>	Cochlin; cochlear and vestibular function
DFNA10	<i>EYA4</i>	Threonine, tyrosine phosphorylase; required for postnatal organ or Corti function
DFNA11 (DFNB2) (USH1B)	<i>MYO7A</i>	Myosin VIIA; stereocilia organization and hair cell contractility
DFNA13 (DFNB53)	<i>COL11A2</i>	Collagen 11A2, fibrillar ECM protein
DFNA15 (overlaps DFNA54)	<i>POU4F3</i>	A POU domain gene; DNA transcription factor; involved in terminal neural cell differentiation
DFNA17	<i>MYH9</i>	Nonmuscle myosin heavy chain 9; interacts with actin cytoskeleton to regulate cell polarity and cytokinesis, causes cochleosaccular degeneration
DFNA20/26	<i>ACTG1</i>	$\gamma$ -Actin; cytoskeletal nonmuscle actin expressed in hair cells
DFNA22 (DFNB37)	<i>MYO6</i>	Unconventional myosin; membrane trafficking, recycling, endocytosis and cell movement
DFNA28	<i>GRHL2</i>	Grainyhead, Drosophila homologue 2; transcription factor expressed in cochlear epithelial cells
DFNA36 (DFNB7/11)	<i>TMC1</i>	Transmembrane channel-like protein 1; required for cochlear hair cell function
DFNA39	<i>DSPP</i>	Dentin sialophosphoprotein; noncollagenous matrix protein; some kindreds have dentinogenesis imperfecta
DFNA44	<i>CCDC50</i> <sup>a</sup>	Ymer; promotes EGF-mediated cell signaling
DFNA48	<i>MYO1A</i>	Unconventional myosin IA; molecular force sensor
DFNA50	<i>MIR96</i>	Micro RNA 96; proposed to regulate functionally necessary gene expression in cochlear hair cells
DFNA51	<i>TJP2</i>	Tight junction protein 2; organization of intercellular junctions, may interact with claudin
DFNA64	<i>SMAC/DIABLO</i>	Direct IAP-binding protein with low pI; promotes caspase activation in the mitochondrial cytochrome C apoptosis pathway

<sup>a</sup>These genes may be associated with low-frequency hearing loss.

cytoskeletal deterioration with age. DFNA22 is caused by a mutation in the gene *MYO6*, which encodes an unconventional myosin protein (143) involved in intracellular trafficking. DFNA28 is caused by a mutation of another transcription factor gene, *GRHL2* (originally called *TFCP2L3*) (144), which has also been implicated in AR HL (8). DFNA36 is allelic with DFNB7/B11 and is caused by mutations in a novel gene, *TMC1*, encoding a transmembrane protein required for cochlear hair cell function (71). Mutations in *DSPP*, which encodes dentin sialophosphoprotein, are responsible for nonsyndromic, second-third decade onset, high-frequency SNHL at the DFNA39 locus, though some kindreds show an association with dentinogenesis imperfecta, type 1 (145). *CCDC50*, which encodes a unique protein, Ymer, an effector of epidermal growth factor (EGF)-mediated cell signaling, is associated with postlingual, progressive HI at the DFNA44 locus (146). Ymer is widely expressed but may be particularly important in the microtubular cytoskeleton. *CCDC50* mutations result in cytoskeletal disorganization, possibly related to failure of normal downregulation of an EGF receptor. The HI involves the low-mid frequency range initially but progresses to include high-frequency HI over time. DFNA48 is caused by mutations in the *MYO1A* gene, which encodes an

unconventional myosin protein (147), and functions as an exquisitely sensitive tension meter, which is critical to the detection of auditory stimuli and in other important cellular functions (148).

HI associated with *MYO1A* mutations is postlingual, highly variable, typically moderate-severe high-frequency loss, which usually does not progress to profound deafness. Mutations in *MIR96*, which encodes a micro RNA expressed in vestibular and cochlear hair cells, cause HI at the DFNA50 locus because of altered expression profiles of genes critical to hair cell function (149). A mouse model of this disorder (150) demonstrated anomalous hair cells and progressive HL in heterozygotes and absent cochlear responses in homozygotes. An inverted genomic duplication including the entire wild type *TJP2* gene is responsible for HL at the DFNA51 locus (151), apparently on the basis of increased apoptosis of auditory hair cells, which may provide a model for age-related presbycusis. A recent report (152) describes HI at the DFNA64 locus resulting from mutation in *SMAC/DIABLO*, which encodes a proapoptotic mitochondrial protein. In addition to genes associated with specific DFNA loci, *CRYM*, which is expressed in the cochlea and vestibule, has also been implicated in AD SNHL (153). This gene encodes the human  $\mu$ -crystallin protein, which is involved in

high-affinity binding of thyroid hormones. HI is thought to be due to impaired Na,K-ATPase-mediated potassium recycling in cochlear fibrocytes (154).

Of great interest, mutations in many of the autosomal NSHL genes cause more than one type of hearing impairment. Mutations in *GJB2* (connexin 26) have been found in occasional families with nonsyndromic ADHL (155), and may also be associated with HI and dermatological findings including KID syndrome. Mutations in myosin VIIA (*MYO7A*) can cause AD nonsyndromic HL as well as Usher syndrome type IB; mutations in *USH1C* cause both DFNB18 and Usher syndrome type IC; mutations in *CDH23* also cause Usher syndrome ID, and some missense mutations are associated with presbycusis; and *PCDH15* mutations cause DFNB23 as well as Usher syndrome type IF. Genotype–phenotype correlation has been demonstrated with missense mutations generally causing the nonsyndromic, milder picture, and nonsense mutations causing Usher syndrome. Some mutations in *SLCA4* (PDS) cause Pendred syndrome. DFNB7/11 and DFNA36 result from mutations in *TMC1*. Mutations in *TECTA* (DFNB21) are also responsible for ADHL associated with the DFNA8/A12 locus (156), which also presents with variable phenotype. Mutations in *MYO6* cause AR HL (DFNB37) and AD HL (DFNA22). Mutations in *COL11A2* may cause AR (DFNB53), AD (DFNA13) or syndromic HL (Stickler syndrome, type III). Autosomal recessive *OTOF* (otoferlin) mutations are among the causes of nonsyndromic auditory neuropathy (76).

Finally, as noted above, dominant mutations in *MYR9*, which has been identified as the cause late-onset HL at the DFNA17 locus, have also been associated with the rare syndrome of congenital large platelets, thrombocytopenia, late-onset SNHL, cataracts and glomerulonephritis (139). In the case of *MYR9*-related disorders, as in the *USH* genes and in a number of other examples of mutations in a single gene causing both nonsyndromic and syndromic HL, clear genotype–phenotype correlations have been established. The importance of variable alleles and modifier genes in the phenotypic expression of deafness genes was reviewed by McHugh and Friedman using the genes encoding cadherin 23 and wolframin as representative examples (157).

### 142.6.3 X-Linked

X-linked inheritance, which is designated DFNX (previously DFN), accounts for only a small proportion (1%) of nonsyndromic deafness. For families in which two or more males have HL, X-linked inheritance should be considered. Because AR inheritance is so much more common than X-linked inheritance, the diagnosis of X-linked deafness should be made with caution, especially when providing genetic counseling. Most cases of X-linked nonsyndromic deafness are sensorineural with congenital, early, or second-decade onset. An important exception is the mixed type of hearing impairment

associated with fixation of the stapedial footplate and raised pressure in the perilymph, which is now designated as DFNX2 (158). Diagnosis of this condition is critical, since a perilymphatic ‘gusher’ with ensuing total HL and onset or worsening of vestibular symptoms occurs when stapedectomy is performed. The gene for this condition has been identified as the transcription factor *POU3F4* (159,160). It is important to note that heterozygous females in DFN kindreds may have later onset of milder, more stable HL than their affected male relatives. Females with DFNX2 are also at risk of perilymphatic gusher, and may receive a misdiagnosis of otosclerosis, leading to the possibility of a disastrous stapedectomy.

DFNX1 is caused by mutations in the gene *PRPS1*, which encodes phyosphoribosylpyrophosphate synthetase 1 (161), which is important for purine and pyrimidine biosynthesis. Abnormal expression of this gene is also associated with three syndromes with HL; X-linked recessive Charcot-Marie-Tooth with HL, ARTS syndrome, and PRPS superactivity syndrome, which have been reviewed by de Brouwer et al. (162), who also suggested the possibility of treatment with S-adenosylmethionine. DFNX4 (formerly DFN6) is caused by mutations in the gene *SMPX* (small muscle protein, X-linked), which is responsive to changes in physical force and may be important in the maintenance of inner ear cells (163,164). At least one other chromosomal locus involved in nonsyndromic hearing impairment, DFNX3, has been proposed to be on the X chromosome. Mutations in dystrophin have been suggested as the etiology of DFNX3, which maps within the Duchenne muscular dystrophy (DMD) gene (165); however, this postulate has not been confirmed, despite evidence from the *mdx* mouse model of DMD, in which SNHL loss is a component (166) (Table 142-4).

### 142.6.4 Auditory Neuropathy

Auditory neuropathy (also referred to as auditory neuropathy/auditory dys-synchrony, AN/AD) is defined as a HL associated with absent or abnormal auditory brainstem evoked responses and or pure tone audiometry in the presence of normal cochlear outer hair cell function, as indicated by preservation of OAEs. The finding of a normal tympanogram, persistent OAEs or CM (cochlear microemissions) and absent ABRs is consistent with a pathogenesis distal to the outer hair cells (i.e. involving IHC and/or auditory nerve). Hence, the lesion must be at the level of the inner hair cells (IHC), the auditory nerve, or the IHC/auditory nerve synapse. Although auditory neuropathy may accompany peripheral neuropathies such as Charcot-Marie-Tooth disease or Friedrich ataxia, it occurs most commonly as a sporadic or autosomal recessive condition. The most common known genetic cause of auditory neuropathy is mutation in the otoferlin gene, *OTOF*, described under DFNB9 and assigned the nomenclature AUNB1 (auditory neuropathy, AR, 1).

**TABLE 142-4 Nonsyndromic X-Linked Deafness (DFNX) Loci**

DFNX1	Postlingual, onset usually 5–15 years in males, fifth decade in females	<i>PRPS1</i>	Nucleotide biosynthesis pathway
DFNX2	Congenital mixed hearing loss associated with stapes fixation and perilymphatic gusher; females may have later onset hearing loss, gusher	<i>POU3F4</i>	Nuclear transcription factor
DFNX3	Congenital profound SNHL; mild-moderate high-frequency loss in adult females	Xp21.2	Gene not identified, may be DMD or is imbedded within the dystrophin gene
DFNX4	X-linked progressive deafness with onset about age 3–7 in males; second to third decade in females with initial high-frequency loss	<i>SMPX</i>	Pressure-responsive protein may protect/maintain cochlear cells exposed to mechanical stress

Recognition of this relatively common cause of SNHL is important and may be hindered in screening programs relying on evaluation of evoked OAEs (76). In addition to the typical congenital, prelingual SNHL associated with *OTOF* mutations, this gene has been associated with later onset, variable and even temperature-sensitive auditory neuropathy (167,168). The only other AR SNHL gene currently associated with auditory neuropathy is *PJVK*, encoding pejvakin, which causes HI at the *DFNB59* locus (see above). While less common, nonsyndromic autosomal dominant auditory neuropathy, *AUNA1*, was described in a large Caucasian kindred with average age of onset at 18 years in presumed heterozygotes and 8–9 years in homozygotes (169). *AUNA1* has been attributed to overexpression of *DIAPH3*, which encodes a member of the diaphanous-related formin family (DRF) of proteins involved in maintenance of cell polarity and cell shape, intracellular transport, and vesicular trafficking, including *DIAPH1* (*DFNA1*) (170). Affected individuals generally present with auditory neuropathy in the second decade, rapid progression to profound HL and loss of OAEs around the fifth decade, though some variability has been described. Although an X-linked auditory neuropathy locus, *AUNX1* has been described in a Chinese kindred (171), it appears to harbor a gene associated with peripheral neuropathy in addition. Finally, auditory neuropathy has been associated with mitochondrial mutation in Chinese patients (172).

### 142.6.5 Modifier Genes

A number of observations in human hearing impairment (especially intrafamilial variability of *GJB2*-related deafness) have suggested the possibility of modifier genes. Examination of mouse models has revealed that a number of genes influence the expression of auditory genes. Mouse genes that modulate HL include *tubby* (*tubby*) and *moth1* (modifier of *tubby* hearing) (173), and *dfw* (deaf waddler) and *mdfw* (modifier of deaf waddler) (174). In humans, a locus for a modifier gene (*DFNM1*) for hearing impairment associated with the *DFNB26* locus has been mapped to chromosome 1q24 (175). Schultz et al. (176) described the gene *ATP2B2*, which encodes the plasma membrane calcium pump protein PMCA2, as a modifier locus for deafness caused by at least two other genes (*CDH23* and *MYO6*) and,

possibly, by noise exposure. Modifier loci also appear to interact with the mitochondrial genome in the etiology of HL (see below).

### 142.6.6 Mitochondrial

Pedigrees with nonsyndromic sensorineural deafness and a maternal inheritance pattern are well known, though the proportion of mitochondrial HL among all nonsyndromic hearing impairment is not clear. While most cases manifest nonsyndromic HL, maternal inheritance of HL in association with diabetes, skin manifestations, neuromuscular symptoms, retinitis pigmentosa and other ocular findings has been reported as well. The most common mitochondrial gene defect leading to nonsyndromic HL is the homoplasmic A1555G mutation in the mitochondrial small ribosomal RNA gene (177). This mutation alone is not sufficient to cause the deafness phenotype, and additional nuclear modifier genes are thought to be necessary for phenotypic expression. Several of these modifier genes have been identified and appear to involve mitochondrial RNA processing (178,179). Importantly, the A1555G mitochondrial mutation also predisposes to aminoglycoside ototoxicity. About 15–30% of patients with aminoglycoside ototoxicity carry the A1555G susceptibility mutation. Hence, review of the pedigree and genetic testing can prevent exposure to aminoglycosides in at-risk maternally related family members of such patients. Four additional mutations in the same small ribosomal RNA gene have also been shown to predispose to aminoglycoside ototoxicity, but occur less commonly than the A1555G substitution (180). Three additional mitochondrial mutations in and around the tRNA<sup>ser</sup> (*UCN*) gene, which lead to nonsyndromic HL, have been identified in pedigrees from all over the world (reviewed by Fischel-Ghodsian (181)). These mutations appear to be nearly homoplasmic in the majority of cases, and the exact pathophysiological relationship between the mitochondrial mutations and HL remains unclear. Of note, a recent study (182) suggested that concomitant use of salicylates, chosen for their antioxidant effect, decreased the risk of aminoglycoside ototoxicity, though it did not address the question of genetic susceptibility in the study cohort. As noted above, some mitochondrial mutations have been implicated in the occurrence of auditory neuropathy. Finally, mitochondrial point mutations,

deletions and duplications have been described in kindreds with SNHL and diabetes mellitus, which occur with significant penetrance but not always together, with or without optic atrophy and/or retinitis pigmentosa, an observation confirmed in population studies of diabetic patients.

## 142.7 SYNDROMIC HEREDITARY HEARING IMPAIRMENT

HL occurs as a primary or occasional component of more than 400 syndromes, many of which occur rarely. The salient features and historical aspects of these conditions have been chronicled in numerous publications and will not be detailed here. The most comprehensive descriptions are provided in the text *Hereditary HL and Its Syndromes* (183) and in *Gorlin's Syndromes of the Head and Neck* (184). As is the case in nonsyndromic HL, syndromic HL is quite heterogeneous at both the phenotypic and the molecular level. This section reviews the major syndromes associated with HL, and provides a categorical approach to the evaluation of the patient with hearing impairment. The most common syndromes can be found in Table 142-5 and will be discussed below.

### 142.7.1 Overview

In general, conductive or mixed hearing impairment, and, in some cases, SNHL should be suspected in any disorder presenting with dysmorphic pinnae, external ear anomalies, known middle ear malformations or craniosynostosis (e.g. oculo-auriculo-vertebral spectrum (OAV), Treacher-Collins syndrome, oto-palatal-digital syndrome, Crouzon syndrome). Children with cleft palate generally develop middle ear effusions shortly after birth and are candidates for surgical ventilation of the middle ears. Those children with syndromic cleft palate are at increased risk of recurrent or persistent middle ear disease if the syndrome is also associated with oropharyngeal hypotonia (e.g. Down syndrome, velo-cardio-facial syndrome), as well as for secondary SNHL. Hence, early and periodic evaluation of hearing and tympanic membrane function is important if these children are to achieve maximum developmental progress. A particularly high frequency of HL is seen in the CHARGE syndrome, in which the HL varies from mild to profound. Temporal bone anomalies, including Mondini malformation and absence or hypoplasia of the semicircular canals, are seen commonly and have been proposed as a major diagnostic criterion (185). The etiology of this usually sporadic condition is heterozygous mutation in the gene *CHD7*, which encodes the chromo-domain helicase DNA-binding protein 7 (186).

Similarly, Kabuki syndrome, which is caused by usually de novo mutations in *MLL2* (187), is associated with HL in 27–45% of patients (188,189). HI in Kabuki

**TABLE 142-5 Common Childhood Deafness Syndromes**

Syndrome	Frequency	OMIM Numbers
Alport	1%	104200, 153640, 153650, 203780, 300194, 300195, 301050, 605249
Branchio-oto-renal (BOR)	2%	113650, 600237
Jervell & Lange-Nielson	1%	220400, 607542
Pendred	1–10%	274,600
Usher	3–5%	27600–276,904, 605,472
Waardenburg	2–5%	148820, 193500, 193510, 277580, 600193, 606662, 608890, 613265, 613266, 611584
Wolfram, WS-like disease (atypical WS)	≤1%	222300, 600965, 604928, 606201, 611507

syndrome may be conductive, sensorineural, or mixed, unilateral or bilateral, and varies in severity. Individuals with disorders of increasing bone density should be evaluated for hearing impairment. Various abnormalities may occur because of compression of cranial nerves as they exit the cranial foramina. Similarly, alterations in the bony labyrinth or ossicles may lead to sensorineural or mixed HL. Hence, hearing should be evaluated periodically in individuals with the severe AR form of osteopetrosis (Albers-Schönberg disease), sclerosteosis, Van Buchem disease, frontometaphyseal dysplasia, metaphyseal dysplasia of Pyle, craniometaphyseal dysplasia, craniodiaphyseal dysplasia, and other rare sclerosing conditions. Many skeletal dysplasias producing disproportionate short stature are regularly or occasionally associated with HL. Achondroplasia, the most common form of short-limbed dwarfism, is frequently complicated by otitis media, particularly in infancy and early childhood. While achondroplasia patients may have malformations of the ossicular chain, the likelihood and severity of conductive HL correlate best with the presence and chronicity of otitis media. SNHL has also been observed occasionally.

About 10% of patients with several types of osteogenesis imperfecta (primarily types III and IV) have severe SNHL, though most are more mildly affected (190). Also, a number of connective tissue disorders, of which the type II collagenopathies (especially Stickler syndrome, discussed below) are most prominent, are associated with SNHL (191). Craniosynostosis syndromes associated with *FGFR2*, *FGFR3* and *TWIST* mutations (Crouzon, Apert, Muenke and Saethre-Chotzen syndromes), and in *RAB23* (Carpenter syndrome) are often associated with mixed or SNHL (see review by Johnson and Wilkie) (192). Finally, hearing impairment occurs in many neurological conditions, inborn errors of

metabolism, conditions with endocrine dysfunction and in a variety of disorders with cutaneous or generalized pigmentary dysplasia, including many ectodermal dysplasias. Hence, hearing should be evaluated in any child with unexplained speech delay, particularly in the face of hypopigmentation of the skin, hair or iris, unusual hyperpigmentation (e.g. café-au-lait macules or lentiginos) or other ectodermal abnormalities.

### 142.7.2 Branchio-Oto-Renal Syndrome

Branchio-oto-renal syndrome (BOR) is an AD condition comprising variable features including preauricular pits or tags, pinna anomalies, lacrimal duct stenosis, branchial cleft cysts or fistulas, renal dysplasia, and sensorineural, conductive, or mixed HL. With an estimated incidence of 1 in 40,000, BOR accounts for about 2% of profound childhood deafness. The HL may have onset in childhood or later, may be progressive in nature, and is often associated with ossicular or cochlear defects, including Mondini malformation and dilated vestibular aqueduct (193–195). At least 6% of affected individuals have severe renal dysplasia, usually associated with hypoplasia (even aplasia), cysts, or structural anomaly of the kidney or collecting system and a glomerular lesion may occur. Thorough audiometric and renal evaluation of family members is indicated when this diagnosis is suspected. Diagnostic criteria for BOR have been established (196). The association of HL and preauricular pits without other findings of BOR has been called branchioto-otic syndrome (BO or BOS), which represents a variant of BOR in which renal disease is absent.

The BOR1 gene, which accounts for about 40% of BOR kindreds, was found to be *EYA1*, the human homolog of the *Drosophila* gene ‘eyes absent’, and one of a family of highly conserved genes (197) that function as both nuclear transcription factors and protein tyrosine phosphatases (198). Expression studies were consistent with a role in inner ear and kidney development. Chang and associates (196) reviewed mutations associated with BOR but were not able to demonstrate genotype–phenotype correlation in BOR/BO kindreds. BOR3, which accounts for about 2% of cases, has been attributed to mutations in the homeobox gene, *SIX1* (199,200), and mutations in *SIX5*, were found to cause BOR2, which accounts for 2.5–5% of cases (201) after a targeted evaluation of *SIX* genes which bind *EYA1*, as the interaction of *EYI1* with *SIX1* and *SIX5* is necessary for gene transcription.

### 142.7.3 Alport Syndrome

In addition to BOR, HL occurs in a number of syndromes in which renal malformation or disease is a major component. After BOR, the most important condition to consider is the Alport syndrome of SNHL and chronic nephritis, which comprises about 1% of all genetic HL

and over 2% of renal transplant patients. The earliest symptom is generally microscopic hematuria with or without proteinuria, followed by slow deterioration of renal function. Microhematuria is typically present in infancy or early childhood in affected males, and episodes of gross hematuria are frequent. Evaluation of the renal ultrastructure demonstrates irregular areas of thickening or attenuation of the basement membrane and interstitial changes. The condition is generally more severe in males, with childhood onset of nephritis and renal failure occurring as early as the second or third decade. Moderate, bilateral, high-frequency SNHL appears by adolescence in the majority of Alport patients, though severe, bilateral SNHL may occur in early childhood. Within pedigrees, nephritis and hearing impairment may occur individually or together, though hematuria precedes recognition of HL, confounding the diagnosis. HL occurs less frequently, has a later age of onset, and is milder in affected females in X-linked kindreds, while gender does not influence age of onset or severity of HL or hematuria in AR or AD families. Ocular defects including congenital cataracts and spherophakia have been noted in at least 40% of male patients, but occur infrequently in AD kindreds. Anterior lenticonus is a pathognomonic finding, and appears to be associated with fragility of the anterior capsule of the lens, which protrudes into the anterior chamber. Kashtan (202) provided a review of the molecular and clinical features of Alport syndrome, including strategies for diagnosis and treatment.

Although as many as five dominant and one recessive Alport syndrome phenotypes have been proposed on the basis of age of onset, presence or absence of HL and other features, X-linked inheritance accounts for about 85% of all cases. Alport syndrome is a type IV collagenopathy, specifically affecting COL4A3, COL4A4 and COL4A5, which are expressed in the cochlear basement membrane, part of the spiral ligament and stria vascularis. Defects in the  $\alpha$ -chain of type IV collagen (COL4A5), which maps to Xq22 and is a constituent of glomerular basement membrane, cause X-linked Alport syndrome (XLAS), and represented the first elucidation of a molecular defect in genetic deafness (203). Renieri and colleagues (204) detected mutations in only 45% of their patients using single-strand conformation polymorphism analysis, suggesting that some of the mutations occur in promotor regions, introns, or alternative splice sites. This observation was confirmed by a nearly 50% detection rate in 131 unrelated Alport patients evaluated for exonic mutations (205). Jais and associates (206) reviewed the natural history of XLAS and provided a review of the clinical features, as well as genotype–phenotype correlations in males from 195 families. Although nonsense mutations and some missense mutations have been associated with juvenile onset of renal disease and ESRD early in the third decade (207), genotype–phenotype correlation is limited for most missense mutations, and identification of most missense mutations is less useful in

interpreting the natural history of the disorder. Detailed genotype–phenotype correlations were reported recently by Bekheirnia and colleagues, who evaluated 681 male subjects from 175 kindreds, and noted that HL, ocular abnormalities and younger age of diagnosis of ESRD were associated with mutations at the 5′ end of the gene (208).

Two contiguous gene deletion syndromes involve the COL4A5 locus. In the association of Alport syndrome with leiomyomatosis of the esophagus and vulva, the COL4A5 and COL4A6 genes are deleted (209,210). The Alport syndrome, mental retardation, midface hypoplasia, and elliptocytosis association (AMME complex) involves deletion of COL4A5, the *FACL4* gene (211), encoding a long-chain acyl-CoA synthetase, and another highly conserved gene, *AMMECR1* (212). The association of Alport syndrome and mental retardation with a contiguous gene deletion in this region was further elucidated by Meloni and colleagues (213). The AR form of Alport syndrome has been associated with abnormalities of COL4A3 and COL4A4 (214) and accounts for up to 15% of cases (215). These genes have also been implicated in AD Alport syndrome, which accounts for fewer than 5% of cases (216,217), and in familial benign hematuria/thin basement membrane disease (218,219). The Fechtner-Epstein syndrome, originally included in the classification of Alport syndrome, has been attributed to mutations in the *MYH9* gene (a nonmuscle, class II myosin heavy-chain gene), which is also implicated in Sebastian syndrome, the May-Hegglin anomaly (220), and *DFNA17* (137,221). Individuals affected with one of these disorders, which are categorized as MYR9-related disorders, present with a variable history of congenital thrombocytopenia with giant platelets, typically postnatal-onset, high frequency, progressive SNHL, presenile cataract, glomerulonephritis with rapid deterioration of renal function and ESRD and neutrophil inclusions, which may be pathognomonic of this group of disorders (222). Striking genotype–phenotype correlations have been described such that the specific type and position of the mutation predicts the natural history of a MYR9-related disorder in a given kindred (139). From a medical standpoint, it is important to differentiate the MYR9-related disorders from Alport syndrome as several treatment modalities have shown promising results in the MYR-9 related nephropathy.

#### 142.7.4 Otosclerosis

The most common cause of HL in adults, otosclerosis, is a focal, immune-mediated disorder of unscheduled bone remodeling affecting the otic capsule. Clinically significant otosclerosis occurs in about 3–4/1000 whites, but is less common in blacks, and rare in Asians. There is a marked female preponderance and symptoms may exacerbate during pregnancy. Conductive, initially low-frequency, HL generally occurs in the third and fourth

decade, but may occur as early as adolescence, and is highly variable within pedigrees. Tympanometry and pure tone audiometry show characteristic patterns. Early in the course of the disease, pathological bone resorption occurs in the otic capsule, followed by formation of spongiform bone, collagen and vasculature. Subsequent progression to dense sclerosis with calcification of the annular ligament and fixation of the stapes in the oval window leads to moderately severe conductive HL. Cochlear involvement occurs in up to 10% of patients and presents with mixed or SNHL. While the medical benefit of sodium fluoride treatment has long been accepted, a critical review (223) found that the data supporting fluoride treatment is weak. Surgical stapedectomy provides improved hearing in greater than 90% of patients, but does not affect the sensorineural component.

Although AD inheritance with markedly diminished penetrance of 25–40% has been accepted historically, examples of kindreds with clear dominant segregation are rare, suggesting that otosclerosis is typically a complex genetic trait with genetic and environmental factors playing a role in its pathogenesis (224). Linkage studies have implicated ten AD loci, but only one potentially causative gene, encoding the T-cell receptor  $\beta$ , has been suggested (224). In addition, three susceptibility genes, which are all part of the transforming growth factor  $\beta$ 1 signaling pathway, *BMP2*, *BMP4*, and *TGF1*, have been identified (225). Recent data also implicates the *reelin* gene (*RELN*) as a susceptibility factor for otosclerosis (226). Although various factors such as estrogens, fluoride and traumatic injury have been associated with otosclerosis, the most important environmental factor is measles virus infection. Measles virus RNA has been isolated from surgically resected stapes footplates in the vast majority of subjects with typical otosclerosis. The importance of measles infection was demonstrated by a study, which showed a significant decrease in otosclerosis in Germany from 1993 to 2004 in individuals with prior measles virus vaccination (227). Sziklai and co-authors state that otosclerosis is an inflammatory disease due to chronic  $\text{TNF-}\alpha$  release in genetically susceptible individuals with persistent measles virus infection in the middle ear (228). They also cite evidence that SNHL may occur because of  $\text{TNF-}\alpha$ -mediated effects on gene expression in sensory epithelium, suggesting the possibility of treatment with anti- $\text{TNF-}\alpha$  antibody.

The differential diagnosis of otosclerosis includes skeletal dysplasias caused by mutations in the gene encoding *noggin* (*NOG*), an antagonist to the bone morphogenic protein gene family, including multiple synostosis syndrome (229), symphalangism type 1, and the syndrome of AD ankylosis of the stapes with broad thumbs, other skeletal anomalies and hyperopia (230). Of note, in the spectrum of conditions associated with abnormalities of *noggin*, stapes fixation is congenital. It is critical to differentiate common otosclerosis and the disorders associated with abnormal *noggin* from XR mixed HL with stapes

fixation and perilymphatic gusher (DFNX2 or Nance syndrome), as DFNX2 patients undergoing stapedectomy develop profuse, continuing drainage of perilymph with resultant increased HL and vestibular dysfunction. Finally, HL associated with osteogenesis imperfecta presents as typical otosclerosis.

### 142.7.5 Stickler Syndrome

Stickler syndrome (hereditary arthro-ophthalmopathy) is a common, extremely variable, AD condition characterized by high myopia, progressive liquefaction of the vitreous with associated risk of retinal detachment, joint laxity, mild spondyloepiphyseal dysplasia with marfanoid habitus and later degenerative arthropathy, characteristic facies, cleft palate, and conductive, mixed or SNHL. The palatal cleft may be of the Pierre-Robin type (U-shaped), and children with this condition are often seen in craniofacial clinics prior to the onset of significant vitreoretinal degeneration or HL. Therefore, it is particularly important to recognize the phenotype and implement an anticipatory care plan to screen for early retinal tears, as laser tacking may prevent retinal detachment. Progressive juvenile or adult-onset SNHL is an integral component of this condition, occurring in as many as 80% of cases.

Some Stickler families, designated vitreous type 1, demonstrate mutations in the type II collagen gene *COL2A1* (231). Another group is subdivided into type II Stickler syndrome, which is associated with a ‘beaded’ appearance of the vitreous and is due to mutations in the *COL11A1* gene, and type III or ‘nonocular’ Stickler syndrome, which is associated with *COL11A2* mutations. Wilkin and colleagues (232) presented evidence for a possible fourth Stickler syndrome locus. Work in mouse models showed that *COL11A1* and *COL11A2* are expressed in the basilar or tectorial membranes (233) and that *COL11A1* mutations act via a dominant-negative

effect (234). Annunen and colleagues (235) provided striking data regarding genotype–phenotype correlations. Compared to that reported for types II and III, mild, nonprogressive HL has been found in type I Stickler (236) syndrome. The auditory features have been reviewed by Admiraal and coworkers (237). Of note, mutations in *COL11A2* are also implicated in a nonsyndromic form of ADHL, DFNA13 (135), as well as otospondylomegaepiphyseal dysplasia (OSMED) and Weissenbacher–Zweymuller syndrome (238). The Stickler syndrome should be differentiated from Marfan syndrome, which has a small associated risk of sensorineural hearing impairment, possibly on the basis of superficial siderosis (11).

### 142.7.6 Waardenburg Syndrome

Waardenburg syndrome (WS) is the single most important disorder combining dermal abnormalities and hearing impairment. As many as 2–5% of deaf children have this condition, making it one of the most common recognizable syndromes associated with hearing impairment. Major features include partial albinism, manifested by poliosis (white forelock, which may acquire pigmentation), premature graying, patchy leukoderma, iris heterochromia (mixed blue-brown eye color in the same or separate eyes), and a relatively blond fundus; distinctive facies with synophrys, dystopia canthorum (lateral displacement of the inner canthi and lacrimal punctae, generally without orbital hypertelorism), an unusual nasal configuration with broad, high nasal root and hypoplastic nasal alae; and congenital SNHL, which is occasionally unilateral (239). Diagnostic criteria delineated by the WS Consortium include five major and five minor criteria (Table 142-6), as well as occasional findings (240).

WS is transmitted as a highly penetrant but variable AD trait, and has been classified into type I (WSI), which accounts for about 60% of WS cases, and type II (WSII)

**TABLE 142-6 Waardenburg Syndrome Type I**

Major Diagnostic Criteria	Minor Diagnostic Criteria
Sensorineural hearing loss <ul style="list-style-type: none"> <li>– Threshold at or greater than 25 dB at two or more frequencies (250–4000 Hz)</li> </ul>	Congenital leukoderma
Iris pigmentary abnormality <ul style="list-style-type: none"> <li>– Eyes of two different colors</li> <li>– Segmental iris heterochromia</li> <li>– Brilliant blue eyes</li> </ul>	Premature gray hair
Hair hypopigmentation <ul style="list-style-type: none"> <li>– White forelock at any age (may repigment)</li> <li>– Dystopia Canthorum</li> <li>– Lateral displacement of the inner canthi</li> <li>– Decrease in visible sclera</li> <li>– Affected first degree relative</li> </ul>	Synophrys or medial eyebrow flare
	Broad, high nasal root
	Hypoplasia of alae nasi
	Rare abnormalities <ul style="list-style-type: none"> <li>– Hirschprung disease</li> <li>– Sprengal anomaly</li> <li>– Spina bifida</li> <li>– Cleft lip and/or palate</li> <li>– Limb defects</li> <li>– Congenital heart abnormality</li> <li>– Vestibular dysfunction</li> <li>– Broad, square jaw</li> <li>– Low anterior hairline</li> </ul>

according to the presence or absence of dystopia canthorum. WSII has about a 50% risk of bilateral SNHL compared to a 25% risk in WSI patients. Absence of the organ of Corti and the stria vascularis, paucity of ganglion cells, and occasional vestibular abnormalities have been described. Madden and colleagues (241) found temporal bone abnormalities, including enlargement of the vestibular aqueduct, in all of their Waardenburg patients with HL. In addition, some patients experience a predominantly vestibular phenotype (242). Type III Waardenburg syndrome (WSIII, Klein-Waardenburg) includes the association of Waardenburg syndrome with musculoskeletal defects of the upper limbs. Cleft lip/palate occurs with increased frequency, as does Hirschsprung disease (aganglionic megacolon), consistent with abnormal migration of cells derived from neural crest ectoderm. The occurrence of WS and Hirschsprung disease with AR inheritance comprises type IV Waardenburg syndrome (also referred to as Shah-Waardenburg syndrome or Waardenburg-Hirschsprung disease). A recent review of molecular studies (243) found that loss of function mutations in the human paired-box gene *PAX3*, which is homologous to the mouse *Pax3* gene, cause WSI as well as the WSIII phenotype, though WSIII may be caused by homozygous or heterozygous mutations. Heterozygous *PAX3* mutations produce the mouse phenotype *Spotch* (Sp), which includes facial clefting, pigmentary abnormalities, and deafness. Of note, homozygous Sp mice have neural tube defects and other neural abnormalities, which are occasionally reported in WSI kindreds. As the *PAX* genes encode DNA-binding proteins, they play a critical role in regulation of transcription. Inner ear development in *Spotch* mice has been reviewed (244).

In contrast to WSI1, WSII demonstrates striking genetic heterogeneity. About 15–20% of cases are associated with heterozygous mutations in the human microphthalmia-associated transcription factor gene (*MITF*), which is analogous to the mouse microphthalmia gene, and is expressed in embryonic retina, otic vesicle, hair follicles, and skin. Mutant mice demonstrate a phenotype similar to WS. *MITF* fulfills several functions in the Wnt signaling pathway (245) and is involved in development and survival of melanocytes (246). *MITF* has also been shown to regulate *DIAPH1*, the gene associated with deafness at the *DFNA1* locus (125), in melanoma cells, suggesting that such regulation plays a role in the HI associated with *DFNA1* and WS2. Sanchez-Martin and colleagues (247) described WSII (labeled WSIIID) in two patients with homozygous deletions of *SNA12*, which encodes the human homolog of *SLUG*, a zinc finger neural crest transcription factor transactivated by *MITF*. *SOX10*, a co-transcription factor that functions in neural crest development, has been implicated as a cause of WSII (248) and WSIV (249). At least one other locus has been suggested by linkage analysis. In addition to *SOX10*, WSIV is caused by mutation in at least two other genes, the endothelin-3 gene (*EDN3*)

(250) and the endothelin-B receptor gene (*EDNRB*) (251). *PAX3* has been shown to regulate *MITF* expression (252), and synergistic interaction between *SOX10* and *PAX3* is required to activate *MITF* expression by binding to the proximal region of the *MITF* promoter (253).

Studies in the dominant megacolon (Dom) mouse document impaired *MITF* expression and subsequent aberrant development and survival of melanocytes in the face of aberrant *SOX10* transcripts (254). Of note, identification of a specific mutation is not usually helpful in predicting phenotype in a given individual, as all of the WS subtypes demonstrate variability within kindreds. WS associated with *SOX10* mutations may also manifest a more complex neurological picture including peripheral and central neuropathy (PCWH) (255). The syndrome of AR albinism, black lock, cell migration disorder causing Hirschsprung disease, and deafness (ABCD syndrome) has been associated with mutations in the *EDNRB* gene (256), and represents a variable presentation of Shah-Waardenburg syndrome. *PAX3* mutations have also been found in the craniofacial-deafness-hand syndrome (257,258) and in one patient originally described as having a mild form of the Yemenite deaf-blind syndrome (259). Molecular studies now allow clear differentiation of WSII from piebald trait, an AD condition caused by mutation in the *KIT* proto-oncogene (260), though some cases lacking *KIT* mutations have been caused by heterozygous *SLUG* deletions (261).

### 142.7.7 Usher Syndrome

By far the most important condition of ocular abnormality and HL is the Usher syndrome, a genetically heterogeneous phenotype in which SNHL, with or without vestibular dysfunction, is associated with later onset retinitis pigmentosa (RP). Usher syndrome was particularly frequent in the Jewish deaf population of Berlin, the French Acadian population of the United States and the Lapp population in Norway. As Usher syndrome may be underdiagnosed, prevalence estimates of 3.0–4.4 per 100,000 appear to be low, as suggested by a recent study, which estimated overall Usher syndrome prevalence to be 1/6000 (262). This common condition accounts for most cases of congenital deafness and RP, which comprise 3–5% of all profound childhood deafness (263,264). In a review of 600 patients from a registry of deaf-blind adults, Boughman and colleagues found that Usher syndrome accounted for 54% of the cases, though it was diagnosed in fewer than half of those individuals (265). There are two common Usher syndrome phenotypes, in which profound, congenital SNHL and vestibular dysfunction are features of type I (USH1), while normal vestibular function, later-onset, usually stable SNHL and progressive RP characterize type II (USH2). The rare type III Usher syndrome (USH3) presents with later onset, generally progressive but more variable deterioration of hearing and vision (Table 142-7).

**TABLE 142-7 Major Phenotypic Features of Usher Syndrome<sup>a</sup>**

Clinical Finding	Usher Type I	Usher Type II	Usher Type III
Hearing loss	Severe-profound, prelingual SNHL	Moderate-severe, nonprogressive	Postlingual, progressive
Vestibular function	Abnormal	Normal	Variable
Retinitis pigmentosa	Prepubertal onset	Pubertal or later	Latest onset

<sup>a</sup>Intermediate phenotypes have been described.

Although the type I phenotype (USH1) was considered to be more common, type II (USH2) accounts for up to 70% of all Usher syndrome patients (266). Genotype–phenotype correlations have been shown for several USH genes that are allelic to nonsyndromic DFN loci, and atypical USH presentations have been documented, often reflecting genotype–phenotype correlations in compound heterozygotes. Male infertility, mental retardation, and psychosis have been noted as well. Posterior cataract, which is a later component of the retinal degeneration, adds to the vision loss. Table 142-7 outlines the major features of Usher syndrome. An observation of abnormal sperm and photoreceptor axonemes led to speculation that defective connecting axonemes in cilia might lead to progressive loss of photoreceptors in Usher syndrome (267). The molecular pathogenesis of retinal degeneration in USH has been summarized recently (268). Because of the importance of this condition, and the difficulty in making an early diagnosis, the Usher Syndrome Consortium defined specific diagnostic criteria (269).

Molecular analysis confirmed marked heterogeneity for USH, with recent data indicating at least 12 loci, for which 10 genes have been identified (reviewed by Yan and Liu (270)). These include seven USH1 loci, four USH2 loci and one locus for USH3. USH1B, which is caused by mutations in the gene for myosin VIIA (271), comprises about 75% of USH1 cases. This unconventional myosin interacts with two other USH1 gene products, harmonin (USH1C) and cadherin 23 (USH1D), to promote transport of membrane-related proteins and intercellular adhesion (272–274). *MYO7A* mutations have also been described in two nonsyndromic forms of SNHL, DFNB2 (61,62) and DFNA11 (64) and in atypical USH cases. The *USH1C* gene product, harmonin, is a scaffold protein, which is a key element in the pathogenesis of Usher syndrome. Harmonin interacts with all of the known USH gene products and with other protein pathways to form a series of protein networks or interactomes involved in diverse functions, including morphogenesis of the hair cell stereocilia and calycal processes of photoreceptor cells, synaptic function; cell polarity and cell–cell interactions and signaling (274). USH1F results from mutations in another cadherin-like gene, *PCDH15*, which encodes a protocadherin and is the human analog of the Ames waltzer mouse. A specific mutation in *PCDH15*, R245X, has been shown to cause most USH1 in the Ashkenazi Jewish population (275). USH1G is caused by mutation in the novel scaffold

protein *SANS*, which is expressed in the cochlea and the eye, whose function is integrally related to that of harmonin (276). The *USH1A* locus has been withdrawn, as SNHL in the original kindreds given this designation has been shown to result from *MYO7A* mutations (277) and the genes for the *USH1E* and *USH1H* genes have not been identified.

USH2A is caused by mutation in a gene encoding an extracellular matrix protein (278,279) called usherin, which is expressed in the cochlea and the retina (280). A founder mutation in *USH2A* is responsible for most Usher syndrome in the Acadian population and French Canadians, illustrating the common origin of these populations (281). One *USH2A* mutation (now noted as 2299delG) accounts for the majority of mutant alleles in British and Chinese families (282), providing a basis for screening for USH2A. The *USH2B* locus has been mapped, but the genes remain unknown. *USH2C* has been attributed to mutations *GPR98* (*VLGR1*), a transmembrane G-coupled receptor (283) and to biallelic, digenic mutation in *GPR98* and *PDZD7*, whose gene product is homologous to the *USH1C* and *USH2D* proteins (284).

*WHRN*, the gene encoding the scaffold protein, whirlin, is implicated in USH2D and ARSNHL at the DFNB31 locus (95). USH3 is caused by mutation in the gene encoding the transmembrane protein, clarin (285), which may be involved in synaptic function of sensory hair cells. Using a mouse model, Geng and colleagues (286) documented expression of clarin in vestibular and cochlear hair cells, and observed postnatal changes implying a critical role for clarin in maintenance of hair cell function and neural transmission. Ocular findings are particularly variable in USH3, sometimes reflecting genotype–phenotype correlations, though marked intrafamilial variation has been observed. Although USH3 has been described primarily in the Finnish population, it occurs in other populations as well. Of note, several of the USH genes, including USH2A, USH2C and USH3, have also been associated with nonsyndromic retinitis pigmentosa (Table 142-8).

Congenital or later onset HL and progressive pigmentary retinopathy occur in a number of other conditions that should be considered in the differential diagnosis of Usher syndrome. Of particular interest to pediatricians is the Bardet–Biedl syndrome (reviewed by Beales and colleagues (287)), a highly heterogeneous AR condition characterized by mental retardation, retinal dysplasia

**TABLE 142-8 Genetic Heterogeneity of Usher**

Classification	Locus <sup>a</sup>	Gene/Protein
Type 1A (USH1A)	14q32	Gene withdrawn
Type 1B (USH1B)	11q13.5	MYO7A/Myosin VIIA
Type 1C (USH1C)	11.15.1	USH1C/Harmonin (Acadian)
Type 1D (USH1D)	10q2122	CDH23/Cadherin 23
Type 1E (USH1E)	21q21	Gene not identified
Type 1F (USH1F)	10q21–22	PCDH15/Protocadherin 15—R245X mutation accounts for most USH1 in the Ashkenazi Jewish population
Type 1G (USH1G)	7q24–q25	SANS/Sans, novel scaffold protein
Type 1H (USH1H)	15q22–23	Gene not identified
Type IIA (USH2A)	1q41	USH2A/Usherin, novel extracellular matrix or cell adhesion molecule
Type IIB (USH2B)	5q14.3–q21.3	Gene not identified yet
Type IIC (USH2C)	5q14	VLGR1/Very large G-coupled protein coupled receptor-1
Type IID (USH2D)	9q32	WHRN/Whirlin
Type III (USH3)	3q21–25	USH3A/Clarin-1, Finnish founder mutation PDZD7/PDZ domain-containing 7, shows digenic modification of USH3A

<sup>a</sup>Other loci are possible.

with or without RP, renal anomalies, polydactyly, hypogenitalism, obesity, and diabetes mellitus, in which HL is an occasional finding. This must be differentiated from the less common Alstrom syndrome of RP, SNHL, obesity, and diabetes mellitus, an AR condition, which is often misdiagnosed or underdiagnosed (288). Both conditions share overlapping features with Kearns–Sayre syndrome, ascribed to mutations in the mitochondrial genome, which presents with varying combinations of optic atrophy with or without pigmentary changes, progressive SNHL, diabetes, cardiomyopathy, generalized myopathy, and other findings. RP and SNHL are integral components of infantile Refsum disease (phytanic acid oxidase deficiency), a degenerative AR peroxisomal disorder characterized by infant-onset deafness and RP, macular dystrophy, peripheral neuropathy, severe developmental delay, hepatomegaly, and mild facial and skeletal dysmorphism; of classical Refsum disease (phytanic acid storage disease), which presents with the triad of later onset RP, peripheral neuropathy, and cerebellar ataxia associated with SNHL, ichthyosis, cardiac arrhythmias, abnormal renal function, and other features (both reviewed by Fournier and colleagues (289)); and of Cockayne syndrome, a heterogeneous AR phenotype comprising dwarfism, mental retardation, skeletal dysplasia, prematurely senile appearance, RP, optic atrophy, deafness, and severe sensitivity to ultraviolet light (reviewed by Nance and Berry, (290)) due to a DNA repair defect.

### 142.7.8 Syndromes with HL and Other Ocular Abnormalities

In addition to conditions resulting in HL plus RP, a large number of conditions combine HL with some other ocular abnormality. Chief among these is the Norrie syndrome, an XR condition characterized by congenital pseudoglioma, iris atrophy, cataracts, synechiae, and blindness, while later onset, progressive, high-frequency

SNHL (291), behavioral abnormalities and mental retardation are common but variable features. Norrie disease represents the most severe end of the spectrum of the group of retinopathies associated with mutations in the gene *NDP*. Milder presentations include some cases of persistent hyperplastic primary vitreous, familial exudative vitreoretinopathy (FEVR), Coats disease, and occasional cases of severe retinopathy of prematurity. *NDP*, which encodes the protein norrin, appears to be a cysteine knot growth factor (292). The ND knockout mouse shows abnormal retinal vascular development, as well as progressive loss of vessels in the cochlear stria vascularis (293) and abnormal signaling of the WNT pathway has been implicated in the pathogenesis of the ocular and auditory phenotypes (294).

### 142.7.9 Pendred Syndrome

Pendred syndrome (PS), an AR disorder combining SNHL variable vestibular dysfunction, temporal bone abnormalities and later onset goiter due to abnormal thyroid hormonogenesis, is the most common condition combining endocrine dysfunction and HL. Most cases of PS, which accounts for 1–10% of hereditary deafness, are caused by mutation in the gene *SLC26A* (formerly *PDS*) (295), whose product, pendrin, is a chloride-iodide-bicarbonate transporter responsible for chloride-bicarbonate exchange and maintenance of endolymphatic potential in the cochlea [reviewed in (296)]. Despite the stereotype of stable, severe-profound congenital HI, HL is variable, may develop in early childhood, and may be mild-moderate in severity, as well as progressive. An early review of 742 published cases found a striking female preponderance (297). Affected individuals virtually always demonstrate abnormalities on temporal bone CT or MRI. In subjects with molecular documentation of Pendred syndrome (PS), dilated vestibular aqueduct (DVA) is present in

80%, absence of the upper cochlear spiral in 75% and absent modiolus in 100% of ears (298). Profound deafness is generally associated with Mondini malformation of the cochlea. Unilateral or mild HL has been described occasionally. Vestibular dysfunction, usually characterized by episodic vertigo and fluctuating HI may occur occasionally and is especially associated with a specific mutation, H723A in *SLC26A4* (299). Three founder mutations in *SLC26A4*, p.Leu236Pro, accounting for 26% of alleles, p.Thr416Pro (15%) and c.1001 + G > A (14%), have been identified in Caucasians (300), and a founder mutation has also been identified in the Japanese population (301). Nonsyndromic deafness associated with EVA (DFNB4) is also caused by mutations in *SLC26A4* (65).

A second gene has been implicated in the etiology of Pendred syndrome. In nine patients with Pendred syndrome or nonsyndromic EVA, Yang and colleagues found heterozygous mutation in *FOXI1*, a transcriptional activator of *SLC26A4*. Causal mutations interfered with *FOXI1* binding, which compromised or completely abolished *FOXI1*-mediated transcriptional activation of *SLC26A4* (302). Furthermore, they described an EVA patient who was a compound heterozygote for mutation in *FOXI1* and *SLC26A4*, implicating digenic inheritance in Pendred syndrome and/or DFNB4. This finding was consistent with a mouse model of this pathway. The thyroid organification defect is mild in PS such that patients are often euthyroid with moderate thyroid enlargement developing in early adolescence. Mild hypothyroidism may precede or accompany the development of goiter, which is inconsistent and appears to be related to iodide intake. Although PS is easily recognized if goiter occurs, it cannot be diagnosed by clinical exam unless there is a known family history. Therefore, in the absence of molecular testing, children with apparently nonsyndromic deafness should be reevaluated periodically for the presence of thyroid enlargement or dysfunction.

### 142.7.10 Neurofibromatosis and Other Neurological Conditions

Although HL is an uncommon feature of neurofibromatosis type 1 (NF1), a formal hearing assessment is warranted, particularly in the face of any learning disability. Progressive, usually adult-onset SNHL and vestibular dysfunction are hallmark features of neurofibromatosis type 2 [NF2], and are associated with unilateral or bilateral vestibular schwannomas. Initial symptoms in NF2 commonly include tinnitus and vestibular dysfunction, which may precede significant HL. Typically, the HL has a subtle, asymmetrical presentation but may be fluctuating, with apparent intermittent improvement. Sudden deafness has been described. Although NF1 and NF2 both occur as AD conditions, it is important to distinguish NF2 (central neurofibromatosis), which is associated with abnormalities in merlin, a tumor suppressor

gene of the moesin–ezrin–radixin family of cytoskeletal proteins (303), from mild cases of NF1 (Von Recklinghausen disease), as the natural history and subsequent anticipatory management are quite different for these genetically distinct disorders. NF2. Diabetes insipidus, diabetes mellitus, optic atrophy, and deafness have been well described as the Wolfram or DIDMOAD (an acronym for the major features) syndrome, an AR condition in which other organ system involvement, progressive neurological deterioration and variable psychiatric symptoms occur as well. Although the onset of symptoms may be in early childhood, diabetes and progressive optic atrophy generally present in later childhood. Diabetes insipidus occurs in about one third of cases and has been attributed to vasopressin deficiency (304). Mild-moderate high-frequency SNHL is a variable feature with usual onset by the second decade, though congenital HI may occur. Most cases of Wolfram syndrome are caused by mutation in *WFS1*, the gene responsible for DFNA6/14/38 (130,131), an unusual nonsyndromic HL predominantly affecting the low frequencies. There is genotype–phenotype correlation with missense mutations associated with DFNA6/14/38 and loss of function mutations in Wolfram syndrome (305,306).

Charcot-Marie-Tooth disease, type 1A, is another important neurological condition in which HL typically occurs in the second decade, with severe hearing impairment noted by the end of the third decade. CMT1A is caused by point mutations in the peripheral myelin protein-22 gene (307). Of historical interest, the Mohr-Tranebjærg syndrome (DDP) of deafness, dystonia, and optic atrophy, which presents initially as nonsyndromic HI, was described originally as an apparently nonsyndromic form of progressive, postlingual SNHL, gaining the designation of DFN1 for the first X-linked deafness locus. DDP is caused by mutations in the gene *TIMM8A*, which encodes the deafness/dystonia peptide (308), a translocase involved in importing proteins into the mitochondria (309,310).

### 142.7.11 Jervell and Lange-Nielsen Syndrome

From an urgent diagnostic standpoint, the most important condition to consider in young children with persistent, profound, prelingual HI is the Jervell and Lange-Nielsen syndrome (JLNS, surdo-cardiac syndrome), a heterogeneous autosomal recessive disorder in which congenital, profound sensorineural deafness is associated with striking prolongation of the Q–T interval on ECG. Affected individuals typically develop arrhythmias, most notably *torsade de pointes* (polymorphic ventricular tachycardia), with resultant sudden death. Children with this condition may be misdiagnosed as having *petit mal* epilepsy or fainting spells, which decreases the likelihood of appropriate intervention, and sudden infant death syndrome may result in under-ascertainment of affected cases.

The syncopal episodes are particularly common in association with stressful activities and exercise, and deaths associated with swimming are not unusual. Although this condition occurs in only about 1% of congenitally deaf children (311), it must be considered in any child with AR or sporadic, profound, congenital SNHL.

Mutations in two related potassium channel genes, *KCNQ1* (312,313) and *KCNE1* (314,315), have been detected in most JLNS families, though there is a possibility of further heterogeneity. Tyson and colleagues (316) presented data indicating that *KCNQ1* mutations account for greater than 90% of cases. Four founder mutations in *KCNQ1* account for the increased prevalence in Norwegians (317). As heterozygosity for a mutation in either of these genes is among the known causes of isolated long QT syndrome (318,319), parents of JLNS children, while not deaf, are presumed heterozygotes for long QT syndrome and require appropriate molecular and clinical evaluation, counseling and treatment. Since JLNS cannot be diagnosed by clinical exam, ECG evaluation is strongly advised in any newly diagnosed child with apparently undifferentiated congenital SNHL, unless another gene (e.g. connexin 26) can be implicated on a molecular basis. Affected children may be candidates for cardiac pacing, which does not contraindicate placement of cochlear implants (320,321), though special attention should be paid to risk of arrhythmias associated with anesthesia (322,323). Although treatment with beta blockade and implantable pacemakers is successful in some cases, even aggressive management does not always prevent a cardiac event. Long term outcome has been reviewed by Swartz and colleagues (324), who also presented data supporting a milder phenotype in individuals with *KCNE1* mutations.

## 142.8 INBORN METABOLIC ERRORS

In addition to the endocrinological and neurological conditions described previously, HL occurs in a number of classical inborn metabolic errors. In particular, SNHL occurs very commonly in biotinidase deficiency, affecting as many as 75% of symptomatic children (325). This disorder of biotin recycling may present with developmental delay, optic atrophy, increased muscle tone, ataxia, seizures, and typical cutaneous manifestations, including alopecia, rash, and mucositis. Biotinidase deficiency is detectable via newborn screening, and its symptoms can usually be averted by prompt implementation of dietary management, including biotin supplementation. Heller and colleagues (326) characterized the CNS localization of biotinidase, and suggested that biotinidase and/or biotin play a significant role in normal hearing. Conductive HL associated with chronic middle ear disease is a regular feature of various lysosomal storage disorders, including mucopolysaccharidosis types I, II, IV, VI, and VII; mannosidosis; the sialidoses (neuraminidase deficiency); and multiple sulfatase deficiency. Progressive

SNHL is a feature of Tay-Sachs disease as well as Refsum disease, and may be a late manifestation of other storage disorders with CNS degeneration, including the disorders of peroxisome biogenesis (Zellweger syndrome spectrum). Progressive or sudden-onset SNHL is particularly prevalent in both males and females with Fabry disease (327,328). Current data suggests that enzyme replacement therapy may stabilize cochlear function and stabilize or improve vestibular function (329). It is particularly important to seek and aggressively treat HI in mild neurological disorders or CNS-sparing conditions as HL significantly increases the disability in these patients.

## 142.9 DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

The assessment of a child with hearing impairment is complex, and requires the interaction of several medical specialists, usually including at least an otolaryngologist, geneticist, audiologist, ophthalmologist, and pediatrician. It helps if the primary care physician serves as a medical home and takes the responsibility for coordinating the evaluation and communicating the overall implications of the findings to the family. The purpose of this multidisciplinary assessment is to identify the most likely cause for the HL, and to evaluate the severity and functional incapacitation associated with it.

The aims of diagnosing the precise cause of HL are:

- To prevent, if possible, further HL.
- To predict associated clinical manifestations, possibly prevent some of the medical complications by early intervention, and to identify associated features that might interfere with the normal social and professional adaptation to the HL.
- To provide genetic counseling for the parents of a deaf child and for deaf adults.

Providing an exact description of the nature and severity of the HL will hopefully allow optimal therapy.

### 142.9.1 History

The initial history should concentrate on the age of onset, progression, and quality of HL, as well as speech ability. In conductive HL, sounds appear quieter but are not distorted. The quality of speech is well maintained, since the patient hears his or her own voice well. By contrast, in sensorineural deafness, sound not only appears quieter but is also distorted. The most frequent distortion is loss of high frequencies, which diminishes the intelligibility of consonant sounds, with resulting difficulties in understanding speech. In severe sensorineural deafness, the patient does not hear his or her own voice, which leads to speech impairment. Discrimination of speech is better conserved with cochlear defects than with retrocochlear defects. The past medical history should document the

pregnancy, labor, delivery, and neonatal history, as well as previous hospitalizations, surgeries, and medications. The review of systems should be exhaustive, since deafness can be associated with signs and symptoms in many different organ systems. Having a check list with specific questions which pertain to the more common syndromes associated with HL ensures that all relevant points are elicited, for example asking directly for a white forelock at birth, premature gray hair, two differently colored eyes or constipation may lead to a diagnosis of Waardenburg Syndrome. Such findings are often quite subtle and may not be mentioned by the patient or parent without direct inquiry. Specific attention should be paid to the age at which a hearing-impaired child begins to walk, as a delay in achieving this milestone may be the first sign of a significant abnormality of vestibular function. Lastly, the family history should investigate the history and physical features of all relatives similar to the patient, and consanguinity should always be considered.

### 142.9.2 Physical Examination

A detailed physical examination of the patient and, sometimes, of close relatives is required, since many of the features of syndromic deafness can be missed in a cursory examination. Also, some critical features of specific syndromes may appear only with advancing age. Particular attention should be paid to the examination of the eyes, cranial nerves, neck and skin. Examination of the ears starts with an examination of the external ear, the auditory canal, and the tympanic membrane. Tuning fork tests are easily performed, and usually allow differentiation between conductive and sensorineural HL. The tuning fork is struck against a firm surface, and then either the fork is held in front of the external acoustic meatus (air conduction) or the base of the fork is held firmly against the skull (bone conduction). More detailed testing is rarely performed outside the otolaryngology office. Lastly, the physical examination should also assess the vestibular system, which is usually done by the Romberg test and an evaluation for nystagmus. The Romberg test requires the patient to stand with eyes closed and feet together, which is only possible with normal proprioception and vestibular system. Nystagmus is defined as an involuntary deviation of the eyes away from the direction of gaze. There are three main types of nystagmus: central, ocular, and vestibular. Vestibular nystagmus has a slow movement away from the line of vision, with quick return due to central correction. Vestibular nystagmus can be spontaneous, positional, or induced by rotational, visual, or caloric stimulation.

### 142.9.3 Laboratory Tests

Patients with childhood deafness require specialized laboratory testing. Most of the tests are performed to categorize the HL and to detect evidence of specific features

associated with the common deafness syndromes. In a minority of cases specific tests are done to detect evidence of acquired causes. These commonly used tests include:

- Otolological: audiometry (pure tone, speech, acoustic impedance), auditory brainstem response, temporal bone computed tomography scan or magnetic resonance imaging
- Vestibular: VEMP (Vestibular Evoked Potential)
- Ophthalmological: refraction; electroretinogram
- Cardiac: EKG
- Endocrine: thyroid function tests, other hormone analysis as indicated
- Renal: urinalysis, blood urea nitrogen, creatinine, renal ultrasound
- Infectious: viral cultures and serology or virus-specific DNA testing
- Genetic: DNA studies (e.g. *GJB2* and *GJB6* mutation analysis), evaluation of multiple genes using chip technology, chromosome analysis or chromosomal microarray as indicated

Since many of the nonaudiometric studies are familiar to the general physician, we describe only the audiology tests. This summary is not intended as an exhaustive description of the complex methodologies used, but only as an aid to assist the geneticist and pediatrician in the interpretation of the results obtained in a general audiological examination.

### 142.9.4 Pure Tone Audiometry

Pure tones of variable intensity and frequency are delivered to the ear by a headphone placed in the ear (air conduction) or on the mastoid (bone conduction). The patient signals whenever he or she hears a sound. It is important to use noise to mask the better hearing ear in both air conduction and bone conduction tests.

### 142.9.5 Speech Audiometry

A series of phonetically balanced words played from a tape recorder is presented to the patient at different intensities via headphones, and the patient repeats each word. The speech reception threshold is reached when 50% of the words are correct. In SNHL, there is often a loss of discrimination with increasing loudness.

### 142.9.6 Management

Management of the child or adult with HL varies depending on the presence or absence of additional findings, and the nature and severity of the HL. The goals of the physician provider should include distinguishing between syndromic and nonsyndromic or isolated deafness whenever possible, determining the etiology of the HL, developing and implementing a tailored anticipatory care plan designed to minimize morbidity related to

both HL and associated features, and providing appropriate genetic counseling to the patient and/or family. As noted previously, careful prenatal and postnatal history, detailed physical examination, and general or targeted examination of parents and/or siblings of an affected child are critical in detecting subtle historical or physical findings that are directive toward a diagnosis. Specialized testing (e.g. serological studies, echocardiogram, renal ultrasound, ophthalmological evaluation, skeletal or other radiographs) should be utilized whenever a specific syndrome is suspected, and should be considered in children with multiple malformations, unexplained dysmorphic features, or suspicious family history. Ideally, evaluation of the child with permanent HL should be accomplished in a multidisciplinary team (330). Recommendations for the genetic evaluation of children with congenital HL have been published in a policy statement from the American College of Medical Genetics (331). Molecular testing for a growing number of complex syndromes and nonsyndromic HL genes including GJB2 and GJB6 (connexin 26 and 30), SLC26A4 (Pendred syndrome and DFNB4), WFS1 (Wolfram syndrome and DFNA6/14/38), and for the various genes implicated in Usher syndrome is available on a service basis, and advanced molecular technology has facilitated evaluation of a larger number of genes in one test. Clinical laboratories also offer testing for known mitochondrial mutations associated with aminoglycoside ototoxicity. Several publications highlight the importance of testing for GJB2 and GJB6 (332,333), and include recommendations for a stepwise approach to molecular testing, though multigene panels may be more efficient and cost effective. SLC26A4 should be evaluated in children with an enlarged vestibular aqueduct or Mondini defect noted on a CT scan or MRI of the temporal bone region.

Since some common conditions such as the Pendred syndrome, JLNS, and Usher syndrome present initially as undifferentiated HL, at least in the absence of affected family members, a single ECG, imaging studies of the temporal bone and ophthalmological assessments can be justified, particularly for those patients whose molecular studies are negative for GJB2 and GJB6 mutations. Ophthalmological assessment is particularly indicated in children with profound SNHL and vestibular dysfunction, in whom the diagnosis of Usher syndrome type I is a consideration, as the genetic counseling and management issues are significantly different from those related to isolated nonsyndromic deafness. As infants with vestibular dysfunction are usually delayed in achieving their gross motor milestones, especially walking, such children may be referred for evaluation of 'developmental delay'. Children with clefting or other craniofacial malformations should be evaluated and followed by experienced personnel in a multidisciplinary craniofacial team setting. Genetic assessment and counseling should be provided as part of the team visit or by referral. Specific medical problems can be addressed as for any other patient and

will often require referral to additional specialists (e.g. referral of Alport patients to a nephrologist).

While the cost-effectiveness of early cochlear implantation has been established (334), complex issues such as the potential benefit of cochlear implantation in a given child, choice of the device, and surgical approach (335) should be deferred to an experienced otologist or to an appropriate subset of the craniofacial team. It is important to note that many forms of nonsyndromic HL, which are associated with normal cochlear development, are amenable to cochlear implant. This approach has become an important treatment modality for children with GJB2-associated HL and children with JLNS are candidates for cochlear implant even when they have pacemakers.

### 142.9.7 Screening for HL at Birth

Universal newborn screening (NBS), proposed as a means of early identification of the at-risk child, is now a standard practice in the United States and many other western world countries. Historically, NBS was supported by a National Institutes of Health Consensus Statement as early as 1993 (336). A later US Department of Health and Human Services publication describing the proposed screening process advocated the immediate implementation of widespread programs (337). Technological advances in automated newborn hearing screening technology, and a series of successful demonstration projects (338) resulted in the introduction of universal newborn hearing screening throughout the US in the mid- to late nineties. Early Hearing Detection and Intervention Programs (EHDI) in the United States are now characterized by reasonable per-infant costs for screening using noninvasive physiological tests, nursery-based screening rates of at least 95% of all infants, and referral rates for diagnostic testing of less than 6% (low false positive rates) (339). Children who 'fail' the newborn hearing screen are then tracked and audiological diagnostic testing is performed; the goal is to provide appropriate therapeutic and educational intervention for these infants by the age of six months. Since these children with HL are identified at a much earlier age, the incorporation of an etiological focus to the diagnosis of the HL, which includes genetic evaluation, testing and counseling, can be of great benefit to the family. The benefits of universal screening and early identification and treatment of the deaf child are well established (340,341). For newborn screening to be successful, crucial issues such as early hospital discharge, home birth, limitations of testing in small or geographically remote units, the need for retesting, referral, formal evaluation of children who fail the initial screen and lack of parental compliance must be addressed.

Establishing protocols for accurate diagnostic evaluation of the child with permanent HL and a laboratory basis for molecular evaluation of such children is critical. Appropriate intervention programs must be implemented

in a timely manner. With this in mind, the Joint Committee on Infant Hearing has set three goals: screening should be completed by one month of age, diagnosis of persistent HL should be made by three months, and intervention and treatment should commence by six months (342). Finally, educational materials, support services, and genetic counseling must be available for their parents. Although we are very successful in screening all infants by one month of age, recent data from CDC suggests that more than 50% of infants who fail hearing screening do not have a documented diagnosis of HL, and of those who do have a confirmed diagnosis of permanent HL, only 77% enroll for intervention by age six months (343). These findings underscore the need to establish a medical home for infants who do not pass their hearing screen, to help the families navigate through the follow-up and diagnostic processes. A workshop in January 2008 convened by the Agency of Healthcare Research and Quality and its federal partners reported on various aspects of the screening program, which could be enhanced with implementation of more evidence based practice for the benefit of children with early HL (344).

The Center for Disease Control and Prevention (345) has developed a manual that provides guidance for early identification and intervention (EHDI) programs. A review of EHDI programs in the United States (346) summarized their history, benefits, and current status, and noted that nearly 95% of newborns are now undergoing hearing screening in the United States. The review also summarized the experience of three relatively long-standing screening programs (Colorado, Hawaii, and Rhode Island), noting that less than 5% of children with permanent HL at entry to school were found to have passed their newborn hearing screen. Dent and colleagues (347) provided a summary of preliminary data from the Utah universal hearing screening program.

Similar reports describe early experiences with universal neonatal hearing screening in other parts of the world (348–350). Despite some successes, developing countries face multiple problems and limitations in the implementation of neonatal hearing screening (351). Finally, the efficacy of using dried blood spots to implement universal screening for common GJB2 and GJB6 mutations as well as for detection of congenital CMV infection is a topic of great interest and discussion (352–354). In addition to the benefits of early intervention for the affected child, a universal screening program offers the opportunity to identify and counsel at-risk couples prior to the birth of additional affected offspring. While the possibility of population screening for mutations causing SNHL exists, particularly with the detection of common connexin 26 mutations, many issues must be addressed before heterozygote screening can be implemented. The position that routine population screening is premature was underscored by a National Institute of Deafness and Other Communication Disorders (NIDCD)

Working Group (355), which felt that connexin 26 mutation screening was appropriate only in conjunction with a clinical trial and stressed the importance of including the deaf and hearing-impaired community in any effort to determine guidelines and recommendations for genetic testing. A survey of attitudes toward newborn screening and genetic testing for HL demonstrated wide acceptance of such testing among the deaf, hard-of-hearing, and normal-hearing populations (356). Taneja and colleagues (357) presented similar results in their survey regarding attitudes of deaf individuals toward molecular testing; however, they noted significant differences in responses of the deaf community versus the normal-hearing group.

### 142.9.8 Genetic Counseling and Prenatal Diagnosis

The process of genetic counseling for inherited deafness is often a daunting one. The consultand may be the hearing parent of a deaf child, a deaf individual, or even a deaf couple. Barriers to communication are often present, including the counselor's inability to sign and the counselee's muteness. Translators may not be easily available or may add an additional barrier between the counselor and the patient. Of great concern, the pedigree and medical history may contain inaccuracies, family myths, and instances of coincidental HI unrelated to the diagnosis in the patient. Even in the presence of a positive family history, the HI may be attributed to a variety of nongenetic circumstances such as trauma, fever, maternal rubella, or meningitis. As many syndromes demonstrate considerable intrafamilial variation, they may be difficult to diagnose without direct physical assessment of more distant family members. Likewise, late-onset conditions often escape detection or accurate diagnosis, and may present subsequent to the initial genetics evaluation of a given family member. Finally, the cultural fabric of the deaf community differs from that of the hearing world, and is generally poorly understood and underappreciated by hearing counselors. While some deaf patients would be relieved to learn that the risk of HL is low in their offspring, others would prefer deaf children or have little concern about this issue. As in any other situation, accurate genetic counseling depends on the accuracy of the diagnosis. In the presence of a clear-cut Mendelian diagnosis, risk assessment is relatively straightforward. In many instances a precise diagnosis cannot be established, and empirical risk figures must be used. For example, when a first affected child is born into a nonconsanguineous family with negative history for deafness, the empirical recurrence risk is about 10%, which reflects the recurrence risk of 25% if the inheritance is AR, or near zero if it represents a sporadic case due to a new mutation or an environmental exposure. Similarly, the empirical risk for a family with two deaf unrelated parents is 10%,

which reflects risks ranging from 100% if both parents have the same kind of AR deafness to 0% if they have different types of AR deafness, with many intermediate risk figures for different inheritance patterns. The empirical risk for families with only one deaf parent is around 5%. Another situation that occurs occasionally in genetic counseling is the normal-hearing couple who have two boys with deafness, raising the question of whether the inheritance is X-linked, and whether prenatal sex determination would be useful. An AR mode is more likely because AR deafness is so much more prevalent. With the demonstration that connexin 26 mutations represent the single greatest cause of AR HL and the availability of evaluating multiple genes at fairly reasonable cost, molecular testing has proved helpful in refining the risk assessment in a significant proportion of these cases.

Prenatal testing is possible in some instances of syndromic and nonsyndromic deafness. Improved ultrasound imaging of the fetus now leads to routine detection of fairly subtle malformations (e.g. microtia, abnormal hand posture), thus allowing diagnosis of specific syndromes that are not amenable to diagnosis by other means. Since molecular testing by direct mutation analysis can be used in those instances in which the precise gene defect has been identified, identification of a connexin 26 mutation, or a mutation in another deafness gene offers the possibility of molecular analysis of fetal cells. Some cases of both syndromic and nonsyndromic HL can be diagnosed by linkage analysis, which is especially applicable to large kindreds with multiple affected family members, especially if the causative gene has not been identified. Ideally, evaluation of the family should be completed prior to pregnancy. The availability of specific prenatal testing may or may not be important to the consultand, and implementation of testing remains a highly personal decision, which should be considered only after extensive genetic counseling.

### 142.9.9 Treatment

The treatment options for genetic HL depend on the precise type and severity of hearing impairment. Conductive HL can frequently be improved significantly by surgical repairs of the external ear and auditory canal, tympanic membrane, and ossicular chain. Hearing aids are the most commonly used treatment modality for SNHL, and have greatly improved performance through the use of more sophisticated circuitry, which allows some devices to fit within the external auditory canal. If conventional hearing aids are not sufficient, cochlear implants, which provide direct stimulation of the auditory nerve, have shown benefits in many patients with profound HI, and current practice includes cochlear implantation in many children with profound prelingual SNHL.

Treatment should always include the prevention of psychological, social, or academic difficulties associated

with HI. Training in cued speech, speech reading, sign language and use of sound and signaling devices plays a role in the prevention of complications due to HL. An understanding team of health professionals can provide important support for both the patient and the family in addressing these issues. Therapeutic intervention for associated findings may improve quality of life, particularly in those conditions in which deafness is associated with vision loss. Vitamin A therapy decreases the rate of retinal degeneration in hereditary retinal dystrophies (reviewed by Weleber and colleagues (358)), though specific efficacy in Usher syndrome is not well established. A report describing the benefit of a caspase-3 inhibitor in reducing retinal photoreceptor cell death in tubby mice, a suggested model for USH1, raises the possibility of a targeted treatment for retinal degeneration in human USH1 patients (359). Potential prophylactic treatment of otosclerosis with anti-TNF- $\alpha$  has already been described, as has S-adenosylmethionine supplementation in DFNX1 (see above). Reduction in the size of vestibular schwannomas and increased language discrimination has been achieved in some type 2 neurofibromatosis patients by treatment with bevacizumab (360). Optimistic early reports of possible regeneration of hair cells in the cochlea have not yet led to fruition. Izumikawa and colleagues (361) reported restoration of hearing by genetic manipulation of nonsensory cells in deafened mature guinea pigs. They documented ‘transdifferentiation’, which was induced by expression of the gene *Atoh1*, a critical regulator of hair cell development. While these investigations are still preliminary, the rapid rate of progress in gene identification is encouraging. The advances in hair cell regeneration and the role of gene therapy in treatment for deafness have been reviewed recently (362,363). The future holds hope that, with further elucidation of the molecular basis and specific pathogenesis of various causes of HL, improved screening and prevention strategies, as well as new therapies for specific defects, will become a reality.

## Biographies

**Dr Falk** is a clinical geneticist who is board certified in Pediatrics, Clinical Genetics and Clinical Cytogenetics. Her major interests include the clinical and molecular aspects of classical chromosome disorders and microdeletion syndromes, genotype–phenotype associations in genetic disorders, prenatal diagnosis, teratogenesis and hereditary hearing loss. She has contributed to the understanding of mitochondrial mutation in aminoglycoside ototoxicity, to the identification of genetic loci for nonsyndromic clefting, Van der Woude syndrome and Stickler syndrome, and to the development of the ACMG Policy Statement providing genetic evaluation guidelines for the etiological diagnosis of congenital hearing loss. Currently, she is involved in studies of the clinical, ethical and social issues associated with use of donor gametes.

**Dr Pandya** is a physician scientist, board certified in Pediatrics, Clinical Genetics and Clinical Molecular Genetics. She has been involved in research on genetic hearing loss (HL) for more than a decade, and has participated in the development of national guidelines for the management of a child diagnosed with hearing loss. Her early career included studies of genetic modifiers of HL in individuals with Waardenburg syndrome. Subsequently, she was involved in identification of new recessive and dominant genes for nonsyndromic deafness, determining the molecular epidemiology of GJB2 deafness and establishing the largest national repository of DNA from deaf individuals. More recently she has focused on assessing the ethical impact of new discoveries in genetic hearing loss on deaf individuals and their families.

## Clefting, Dental, and Craniofacial Syndromes

*Jeffrey C Murray and Mary L Marazita*

The University of Iowa, Iowa City, IA, USA

### 143.1 INTRODUCTION

Craniofacial anomalies comprise a large fraction of morbid human birth defects. They require surgical, nutritional, dental, speech, medical, and behavioral interventions and impose a substantial economic and societal burden (1). Clefting, or an aberrant space between normally fused tissues, usually occurs as either cleft lip with or without cleft palate (CL/P) or cleft palate only (CPO). Rare forms of clefts, such as lateral facial clefts extending into the orbit or laterally from the oral cavity, also occur. Clefts of the lip and/or palate can be divided into non-syndromic (isolated) and syndromic forms. In isolated clefts, affected individuals have no other physical or developmental anomalies. Studies suggest that about 70% of cases of CL/P and 50% of cases of CPO are non-syndromic (2,3). The syndromic cases can be subdivided into more than 500 Mendelian disorders (e.g. OMIM (4)), cases due to chromosome anomalies or to teratogens, and uncategorized syndromes. The complex etiology of clefting affords opportunities to identify gene–gene or gene–environment interactions that can shed light on human embryology and its disturbances (5–7).

### 143.2 DEVELOPMENT

In humans, an exquisitely choreographed cascade of gene expression, cell migration, cell transformation, and apoptosis between 14 and 60 days postconception creates the tissues of the face from the originating oropharyngeal membrane. Neural crest cell migration drives the swellings that form the frontonasal prominence and the paired maxillary and mandibular prominences. Fusion of the prominences results in normal facial relationships. By 48 days the upper lip is continuous, and by 60 days palatal shelf fusion completes facial embryogenesis (8–10). Disruption of any of the tightly regulated processes occurring in this time frame may predispose to cleft lip and/or palate. Genes with a demonstrated role in these

processes include those for transcription factors, growth factors, cell signaling molecules, and extracellular matrix proteins (7). Embryology suggests that clefts of the primary palate that involve the lip with or without the palate (CL/P) result from different disruptive mechanisms to clefts affecting only the secondary palate (CPO) (11). However, lumping of CL/P and CPO in etiological studies has recent support in that both CPO and CL/P are found in families segregating mutations of *MSX1* (12), *IRF6* (13), or *FGFR1* (14). In addition there is also support for separate mechanisms for clefts of the lip only, as distinguished from clefts involving the lip and palate together (15).

### 143.3 EPIDEMIOLOGY

CL/P affects about one in 700 births, with wide variability across geographic origin (16,17) and socioeconomic status (18). In general, Asian or American Indian populations have the highest birth prevalences, often as high as one in 500, with European-derived populations intermediate at about one in 1000 and African-derived populations the lowest at one in 2500. CL/P has remarkable differences in frequency by sex and side of clefting. There is a 2:1 male:female ratio and a similar 2:1 left-side:right-side ratio for unilateral clefts. CPO birth prevalence is more constant across groups of different ancestral origin at about one in 2500 but is compromised by ascertainment failure in studies that lack active surveillance programs.

### 143.4 GENETICS

#### 143.4.1 Human Genetics

For more than 200 years, scientists have suggested the importance of inheritance in the etiology of cleft lip and cleft palate. Trew (19) published the first description of a family with several affected members, and

Darwin (20) called attention to a publication (21) with “the transmission during a century of hare-lip with a cleft-palate.” Fogh-Andersen in Denmark was the first to collect a systematic data set of cleft families and to evaluate the observed inheritance patterns (22). His conclusions, that cleft families were consistent with the segregation of alleles at a single genetic locus with variable penetrance, were subsequently supported by segregation analyses (23) and twin studies (24). In the 1960s and 1970s, a particular statistical model termed the **multifactorial threshold model** was invoked to explain the familial patterns of oral-facial clefts, with recent support coming from a large, population-based study in Denmark (25). The identity of facial structures observed in normal monozygotic twins supports a strong genetic component to facial development. However, the lack of complete concordance for clefts in monozygotic twins (50% concordance versus 8%) in dizygotic twins argues that other factors (environment/stochastic) must play a role as well. Evaluation of sibling recurrence risk ratios estimates that  $\lambda$  for siblings is approximately 40. Schliekelman and Slatkin (26) estimated the number of loci contributing to the genetic component of CL/P as between three and six, although the confidence interval for the best estimate extended to 14 loci.

The emerging consensus of the genetic component of non-syndromic orofacial clefts is that relatively few genetic loci with common variants contributing to clefting are involved, with heterogeneity from family to family (or between populations), interacting genes, and rare variants and/or epigenetic factors also playing a role. Many investigators have used candidate gene, linkage and association approaches with new efforts now expanding to genome wide association and deep sequencing (candidate region, whole exome and whole genome) (7,27).

### 143.4.2 Linkage and Association Studies

Genetic investigation strategies for clefting have been recently reviewed (7). Linkage studies of clefting have led to the identification of one strong candidate, FOXE1, supported by the linkage, mutation identification and expression data (28–31). A few other candidate genes (32–35) continue to be of interest, based on candidate gene association work and/or sequencing studies, but other than IRF6 none has been replicated in genome-wide association studies GWAS (see below) so their specific contributions remain to be better defined.

Association studies using case-control or case-parent triads have also been used to examine candidate genes in CL/P for over 20 years (36–38). Only one gene, *IRF6*, that is etiological in the autosomal dominant Van der Woude syndrome (13) has consistently shown association in replicated studies (see below). Recently, GWAS have had striking success in finding new loci for clefting and have been recently reviewed (7,27).

### 143.4.3 Evidence from GWAS

Four published GWAS efforts have now made substantial contributions to our understanding of the loci/genes in which common variants contribute to non-syndromic clefting (39–42). They have each identified or confirmed a new locus at 8q24 as having a strong association with cleft lip and/or palate in European populations, strongly support a role for variants near the *VAX1* gene in clefting and identify new loci near the *MAFB* and *ABCA4* genes as having variants contributing to clefting seen most strongly in Asian populations. In one case (*MAFB*), additional functional and expression data support that gene as the best candidate (42). For the others, the specific gene and contributory SNP remain to be identified. It is also evident from other studies that it is likely that rare variants (as well as other genetic and environmental contributors) will also play a role in clefting, and currently applicable technologies such as whole exome or whole genome sequencing are likely to be used in studies of complex traits, including clefting.

### 143.4.4 Animal Models and Expression Studies

The strongest cleft candidate genes will include those in which normal expression of that gene takes place at the critical time and in the critical tissues for lip and palate development. Animal models and expression data can be powerful tools to identify candidate genes for a complex trait such as CL/P (43).

GWAS or linkage studies may identify regions containing tens or even hundreds of genes that could be causative, and so a priority list must establish the order in which to evaluate genes to confirm their etiological role. Animal models with spontaneously arising clefts or from knockout or ENU experiments can help to provide a list of genes on which direct sequencing can be carried out as confirmation steps. While cleft palate is a common phenotype in the mouse, cleft lip is rare. Two spontaneously arising cleft lip mutants, *Clf1* and *Clf2*, were identified in a genome-wide scan for susceptibility loci in the mouse using strain A/WySn (44), with an insertion into *Wnt9* as a likely mechanism affecting epigenetic regulation (45,46). Another mutant with high penetrance for cleft lip is *Dancer*, which arises from a translocation of p23 sequence into *Tbx10*, resulting in ectopic expression of *Tbx10* under the influence of the p23 promoter (47).

Global approaches to expression analysis of genes in craniofacial structures have begun to provide a broader view of gene function as well. First, the COGENE project ([hg.wustl.edu/COGENE/](http://hg.wustl.edu/COGENE/)) provides public web access to human gene expression data for 24 craniofacial-specific human tissues isolated from day 26 to day 60 embryos. The expression of genes relative to each other in both time and space is being visually represented using optical projection tomography (OPT) (48). OPT can be used

to evaluate the expression of new candidate genes and to demonstrate that the expression of existing genes is consistent with hypotheses about function. Expression profiling is now providing evidence for interacting genes and pathways in facial development (49,50). Finally, a newly supported effort by the NIDCR called FaceBase is providing a public website (<https://www.facebase.org/>) and compiling data to enable a common point source to interested users for data of many types (expression, imaging, phenotypic, genetic) across humans and a range of animal models (51).

#### 143.4.5 Environmental Factors and Gene–Environment Interactions

An environmental component of clefting was recognized when Warkany (52) associated nutritional deficiencies with cleft palate. More recent studies continue to support the importance of nutritional factors (53,54), as well as low socioeconomic status (18). Recognized teratogens that contribute to clefts include rare exposures, such as phenytoin and thalidomide, and also common environmental exposures, such as maternal alcohol or cigarette use (55–57). Increased risks from exposures can suggest metabolic pathways whose disruption may play a role in the development of CL/P. Common variables such as alcohol, smoking, or nutrition may have their effects amplified by pharmacogenetic variation. Studies of gene–environment interactions (58) for non-syndromic CL/P are in their infancy, but some interesting preliminary data support further studies of folate-metabolizing enzymes and genes in detoxification pathways (1,42).

### 143.5 CLINICAL EXAM AND PHYSICAL FINDINGS

Figure 143-1 shows examples of typical facial clefts as well as features associated with two of the more common syndromes: VDWS and ectrodactyly–ectodermal dysplasia and clefting.

#### 143.5.1 Associated Phenotypic Features

Accurate phenotyping is important for any human genetic study. To date, the cleft phenotype has generally been defined as a qualitative trait (i.e. affected or unaffected). However, some studies have begun to examine genetic differences for specific cleft phenotypes; e.g. genome-wide linkage results differ by the specific cleft phenotypes seen in multiplex families (30) and a specific putatively etiological variant in *IRF6* shows greater statistical significance in CL alone than in CLP (15). The spectrum of cleft anomalies includes visible microforms of the lip (e.g. notches or grooves in the upper lip) and palate (e.g. cleft uvula and submucous CP). Of note, microform CL is increased in individuals with *BMP4* mutations (59).

In addition to genetic differences by overt and microform cleft types, it now appears that the spectrum of phenotypes due to orofacial cleft risk factors includes a variety of associated subclinical phenotypic features, sometimes termed endophenotypes, as recently reviewed (60). Such subclinical phenotypes may allow researchers to identify noncleft individuals at increased risk to be carrying cleft genes, or to divide families into more homogeneous subsets, leading to improved power for genetic studies of clefting, and improve ability to provide effective genetic counseling, particularly recurrence risk information.

Subclinical phenotypic features are within the range of normal variability but are seen at increased frequency in individuals with OFC or their relatives, as opposed to controls with no family history of OFC (60). This idea has been present in the literature for many years, with the earliest subclinical phenotype studies focused on laterality measures such as handedness, due to the preponderance of left-sided unilateral clefts. More recent studies have found a range of subclinical phenotypes that are increased in OFC cases and relatives: orbicularis oris muscle defects (61–64); dental anomalies (65); lip dermatoglyphics (66); facial measurements (60,67,68); and brain variants on MRI (69–72). Furthermore, examination of such phenotypes is beginning to blur the historical distinction between CL/P and CP in some cases; e.g. in a small study there was a significant proportion of CP cases with orbicularis oris defects (73).

#### 143.5.2 Clinical Examination

The clinical examination of a newborn or an older child with a cleft of the lip or palate has as its primary focus the determination as to whether isolated clefting or a syndromic form of clefting is present. As is true for any clinical genetic examination, family history, prenatal history, prenatal testing, and postnatal testing are important considerations in addition to the physical exam itself. The clinical exam focuses on both dysmorphology of the head and other regions, and on the parents or siblings when available. Identifiable structural abnormalities such as congenital heart malformations, limb anomalies (ectrodactyly syndactyly, etc.), or central nervous system malformations make syndromic identifications straightforward in some cases. In others the findings may be far more subtle. In addition, there may be overlap between syndrome definitions. For example, mutations in *MSX1* can present with isolated dental anomalies outside the region directly affected by the clefts (e.g. in the lower jaw). Whether cases of clefts with dental anomalies should be considered as isolated clefts can be debated, but the presence of such findings has implications for recurrence risks in families. *MSX1* and *FGFR1* nonsense mutations may present as isolated clefts, but the sibling recurrence risks may be well above the 3%–5% used for isolated clefts in general.

**FIGURE 143-1** (A) A child with bilateral cleft lip and palate. (B) A child with unilateral cleft lip and palate. (C) Lip pits in the lower lip as seen in two cases of van der Woude syndrome. (D) Facial, limb, and hand defects seen in the EEC syndrome.

The distinction between syndromic and non-syndromic is evolving, and a complete exam and family history will increasingly be coupled to molecular analysis. Some specific considerations that are of primary concern would include the possibility of the deletion 22q11.2 syndrome, which can commonly have clefts; VDWS, in which lip

pits may be absent in up to 15% of individuals with mutations; *MSX1* mutations, which can have isolated dental anomalies; and *FGFR1* mutations, which in classic cases cause features of Kallmann syndrome that may be absent in some carrier individuals within an affected pedigree.

### 143.5.3 Genetic Counseling

One of the main concerns expressed in a genetic counseling session is recurrence risk (RR) estimation, that is, the chance that a disorder will recur in a family given the presence of a previous affected individual, with the most common scenario being parents with an affected child. For orofacial clefts, RR estimates can be made with precision for some syndromic forms if they are Mendelian or due to a recognized chromosomal anomaly, but the majority of orofacial clefts are isolated or non-syndromic. As reviewed earlier in the chapter, much recent progress has been made toward identifying specific genetic determinants of orofacial clefts, but as yet there are no genetic tests that could identify carriers of genes that increase the risk of having an offspring with non-syndromic clefts. For such cases, there is still a reliance on empiric RR figures. Empiric RRs are determined by surveying a large number of families with affected individuals and cataloging the percentages of affected relatives (74,75). Table 143-1 summarizes the ranges on RR for non-syndromic CL/P and CPO.

Cleft severity (e.g., bilateral CL/P vs. isolated cleft lip only) and family history can result in an increased risk in offspring as well (25). Interestingly, RR estimates can also be modified by the presence of subclinical phenotypic features in unaffected relatives, for example orbicularis oris discontinuities (76).

### 143.6 CONCLUSION

In summary, clefts of the lip and palate are common and complex human birth defects that have both genetic and environmental causes. Seventy percent of clefts involving the lip appear to be isolated, but we are increasingly recognizing the contribution of single genes to such cases, with *IRF6*, *MAFB*, *VAX1* and a locus at 8q24 as recently identified examples. Molecular genetic tests are not yet available for non-syndromic clefting, so recurrence estimates currently are based on family history and associated clinical features; however, we may soon reach a point at which molecular analyses are appropriate for a broad spectrum of individuals with apparently isolated clefts.

**TABLE 143-1** Empiric Recurrence Risk Estimates (in Percentages) for Isolated Orofacial Clefts

Cleft Lip with or without Palate	Affected Family Member	Cleft Palate
One sibling	1.2–5.1	2–5
Two siblings	9.0–14.0	10–20
Mother	1.9–6.8	–
Father	2.0–4.5	–
One parent (not specified)	1.7–5.0	3.0–7.0
First cousin	0.2–0.5	–
Aunt/uncle	0.4–0.8	–
Grandparent	0.2–0.8	–

### Biographies

Jeffrey C Murray, MD has a longstanding career commitment in understanding the genetic and environmental causes of complex pediatric diseases. He is a trained pediatrician and geneticist in the area of human molecular genetics. He has used human gene mapping approaches and epidemiology to discover the underlying causes of cleft lip and palate. He is the co-director of the NIDCR FaceBase consortium, directs the Craniofacial Anomalies Research Center and oversees the projects on cleft etiology in Denmark, Iowa and the Philippines. These efforts use genome-wide association, linkage and sequencing approaches to identifying genetic causes and then coupling these to environmental covariates.

Mary L Marazita, PhD has many years of experience in applying the techniques of statistical genetics and genetic epidemiology to multiple complex human traits (craniofacial birth defects, oral health traits, and others), including many studies of the genetics and phenotypes in non-syndromic orofacial clefting families. She is also engaged in cross-disciplinary clinical research, and serves as a professor in the University of Pittsburgh Clinical and Translational Science Institute (CTSI). She has made major contributions in identifying genes for CL/P, dental anomalies and understanding the role of subphenotypes in CL/P.

### GLOSSARY

**Craniosynostosis** – craniosynostosis is premature fusion of the sutures leading to abnormal morphology of the skull and can prevent normal brain and neurologic development requiring surgical intervention.

**Fibroblast growth factor receptors** – fibroblast growth factor receptors (FGFR1, FGFR2, and FGFR3) are a group of tyrosine kinase receptors with multiple isoforms, activated by a wide range of ligands and heparin sulfate proteoglycans, and are involved in developmental processes of differentiation, cell growth and migration, and bone growth. Mutations in these receptors are commonly found in coronal craniosynostosis.

**Sutures** – sutures of the skull consist of undifferentiated mesenchymal cells between ossifying fronts of bones. These cells differentiate to lay down osteoblasts at the leading edge of growing bones. The major sutures of the neurocranium include the coronal, metopic, sagittal, and lambdoid sutures, which separate the frontal, parietal, and occipital bones.

**Transcription factor** – transcription factor proteins bind to regulatory regions of genes and require the recognition of RNA polymerase to regulate gene expression. Transcription factors TWIST1, MSX2, RAB23, and RUNX2 are involved in normal embryonic skull development as well as the pathogenesis of craniosynostosis.

### 144.1 INTRODUCTION

Craniosynostosis is defined as the premature fusion of skull bones. This malformation is usually isolated, but can be found in association with human disorders that are etiologically and pathogenetically heterogeneous. More than 100 syndromes with craniosynostosis as a feature have been clinically delineated (1,2). The genetic basis of some isolated cases as well as craniosynostosis syndromes such as Crouzon, Apert, Jackson–Weiss,

Pfeiffer, Muenke, Crouzonodermoskeletal, Beare–Stevenson, Antley–Bixler with or without genital abnormalities and disordered steroidogenesis, Saethre–Chotzen, Baller–Gerold, craniosynostosis Boston-type, craniofrontonasal, Carpenter, and CRSDA (craniosynostosis and dental anomalies) syndromes have been identified (3–11). Mutations have been found in a variety of genes coding for the fibroblast growth factor receptors (FGFRs), TWIST1, RECQL4, MSX2, ephrins, p450 oxidoreductase, ras-associated protein RAB23, and interleukin 11-receptor alpha. These discoveries have elucidated not only the biology of craniosynostosis, but also the biology of normal skull and sutural development.

### 144.2 SKULL AND SUTURAL DEVELOPMENT

The early development of the human skull is marked by three phases: membrane formation, chondrification, and ossification (12–15). Skull formation begins by the third to fourth week of gestation, and the calvarium is distinguished clearly from the vertebral column by the fifth week. The membrane, derived from mesenchyme of the neural crest and paraxial mesoderm, encapsulates the developing brain and ultimately gives rise to the neurocranium. At the sixth week of gestation, chondrification initiates in both the body of the sphenoid and basiocciput and continues until the seventh week, when the dura mater becomes evident. Subsequently, isolated ossification centers come together to form the individual bones of the skull. Direct ossification of the membrane at the top of the developing skull gives rise to the cranial vault, and ossification of chondrocranium gives rise to the base of the skull. Further development of the skull is associated with rapid brain growth, differentiation and vascularization.

At birth, calvarial bones overlap as the human head is compressed through the birth canal. The resultant

molding normalizes during the first week of life by cranial expansion and widening of the sutural areas. These sutures are articulations in which contiguous margins of cranial bone approximate each other and are united by a thin layer of fibrous tissue. As cranial sutures develop during infancy, they adjust to the growing brain with bone deposition at the sutural margins. The sutures prevent separation between bones by external forces such as trauma, but allow for slight adjustments to absorb minor trauma during infancy and childhood. Sutures function to permit growth of the skull yet provides a firm bond between adjacent bones. Patent sutures eventually close with bony bridging.

Head shape depends in part on the developmental stage when fusion of individual sutures occurs. With premature fusion of sutures or synostosis, the head shape is altered (1). Premature closure of the sagittal suture results in dolichocephaly or an oval-shaped skull with an elongated anterior-posterior length. When the coronal sutures are involved, brachycephaly results with a reduced anterior-posterior length of the skull. Unilateral involvement of the coronal or lambdoidal suture produces plagiocephaly, an asymmetric head shape. With unilateral coronal involvement, there is anterior flattening on the side of the synostosis with a compensatory posterior bulge on the contralateral side. With unilateral lambdoidal synostosis, there is asymmetric posterior flattening with a contralateral anterior bulge. Metopic fusion produces trigonocephaly with prominence in the midregion of the forehead. Multiple sutural synostoses may also occur.

### 144.3 GENETIC EPIDEMIOLOGY OF CRANIOSYNOSTOSIS

Craniosynostosis is among the most common human malformations, with a birth prevalence of approximately one in 2500 newborns in European, African, and Asian populations (1). Craniosynostosis most often occurs as an isolated feature although it can also appear in association with other malformations or diseases. The etiological and pathological factors are both environmental and genetic. Conditions with secondary craniosynostosis include metabolic conditions (hyperthyroidism, rickets, mucopolysaccharidoses), hematological disorders (thalassemia, sickle cell anemia), malformations (holoprosencephaly, microcephaly, encephalocele), and disorders of teratogenic (diphenylhydantoin, valproic acid, retinoids) and iatrogenic (rapid decompression of hydrocephalus) causation.

Sagittal synostosis is the most common isolated craniosynostosis due in part to intrauterine constraint and has a birth prevalence of one in 5000 (1). Seventy-two percent of cases are sporadic with a male to female ratio of 3.5:1. Six percent of cases are familial and predominantly of autosomal dominant inheritance with 38% penetrance. Isolated coronal synostosis occurs half as

frequently as isolated sagittal synostosis. Sixty-one percent of cases are sporadic with a male to female ratio of 1:2 and show an association with advanced paternal age. Ten to 14% of cases are familial with autosomal dominant inheritance and 60% penetrance. Isolated metopic synostosis accounts for almost as many cases as isolated coronal synostosis (16,17) and has a birth prevalence of 0.8–1.9 per 10,000. Epidemiological studies have reported an increase in the occurrence of metopic synostosis by as high as four-fold after the last decade compared to the early 1900s, perhaps due to improvement in the recognition of those cases, especially those requiring an early surgical procedure (18,19). There have been other etiological theories, involving genetic and environmental factors, mechanical constraints, pharmaceutical effects, and social factors (20–22). Ten percent of cases are familial primarily with autosomal dominant inheritance. The male:female ratio is approximately 3.3:1, and no advanced maternal or paternal age has been reported (17). All other single suture synostosis, including lambdoid synostosis, and multiple sutural synostosis are much less frequent. Associated anomalies, especially congenital heart, limb, and ear defects, occur more often with coronal synostosis, and there is more known about the genetic bases of craniosynostosis involving the coronal suture than other sutures.

## 144.4 CRANIOSYNOSTOSIS SYNDROMES

### 144.4.1 Crouzon Syndrome

Crouzon syndrome (OMIM #123500) is one of the most common, autosomal dominant conditions involving coronal synostosis. Other common features include midface hypoplasia and shallow bony orbits resulting in ocular proptosis although there is significant variability in expression (Figure 144-1). It is not unusual for more mildly affected family members to go undiagnosed until the birth of a more severely affected child. The birth prevalence is estimated at one in 25,000 births and accounts for 4.5% of all cases of craniosynostosis. Over half of Crouzon syndrome cases occur as new, spontaneous mutations. Germline mosaicism has also been proposed in families with two unaffected parents who had more than one affected child (23,24).

The clinical findings of Crouzon syndrome are generally limited to the head and neck region. This is in contrast to several other craniosynostosis syndromes, in which abnormalities of the hands, feet, or both are common. Crouzon syndrome is characterized by brachycephaly resulting from coronal synostosis. The forehead is often high and prominent. Other common features are hypertelorism, strabismus, midface hypoplasia, a prominent beaked nose, high arched palate, mandibular prognathism, and dental malocclusion (see Figure 144-1). Ocular proptosis is a consistent finding and is due to the

**FIGURE 144-1** Crouzon syndrome. Brachycephaly, ocular proptosis, beaked nose, and midface hypoplasia. (From Tewfik, T. L.; Teebi, A. S.; der Kaloustian, V. M. *Selected Syndromes and Conditions. In Congenital Anomalies of the Ear, Nose, and Throat, 1st ed.*; Tewfik, T. L.; der Kaloustian, V. M., Eds.; Oxford University Press: Oxford, 1997; pp 461.)

development of shallow bony orbits. In extreme cases, subluxation of the globe occurs. The placement of the ocular musculature is affected as well, and strabismus is a common feature. Cervical spine abnormalities, especially fusion of vertebral bodies has been described. The fusion of C2–C3 occurs most frequently. Fusion of tracheal arches (tracheal cartilaginous sleeve) has also been reported (25). Conductive hearing loss occurs in a significant percentage of Crouzon syndrome patients. Intelligence is usually normal. However, in cases where the craniosynostosis leads to significant and prolonged increase in intracranial pressure, intellectual compromise and vision loss may result.

The majority of cases with Crouzon syndrome are caused by missense mutations in fibroblast growth factor receptor 2 (*FGFR2*)(OMIM \*176943)(26).

#### 144.4.2 Jackson–Weiss Syndrome

Jackson–Weiss syndrome (OMIM #123150) is an autosomal dominant disorder of craniosynostosis and bony foot deformities. It was initially described in very large Amish kindred in 1976 (27). The cranial features were quite variable. In fact, the authors felt that within this extended family, the entire range of the cephalosyndactyly syndromes (with the exception of Apert syndrome) appeared to be represented. Midfacial hypoplasia was common, and the skull manifestations ranged from mild prominence of the forehead to severe acrocephaly (Figure 144-2). Radiographic evidence of craniosynostosis was obtained in several affected individuals with apparently normal skull shape. Even in those individuals with severe cranial deformity, intelligence was unaffected.

A common feature in all affected family members was bony abnormalities of the feet. These include broad, medially deviated great toes, and fusion of tarsal bones, with calcaneo-cuboid fusion occurring commonly (see Figure 144-2). Some individuals had no outwardly apparent foot abnormality, yet had bony fusion or other defect revealed on radiograph. Others were noted to have cutaneous syndactyly of the second and third toes. An unrecognized branch of the original family was recently studied, and additional features were noted in affected members, including a leg-length discrepancy and unilateral absence of the fifth digital ray of the foot (28). No individual was found to have bony abnormalities of the hands or thumbs, a feature, which was used to distinguish Jackson–Weiss syndrome from other craniosynostosis conditions.

Jackson–Weiss syndrome is due to missense mutations in *FGFR2* (29). Because this syndrome is allelic with Crouzon syndrome and some patients with either of these two diagnoses can have the identical mutations in the same or unrelated families, these phenotypes are now thought to belong to the clinical spectrum of *FGFR2*-craniosynostosis syndromes.

#### 144.4.3 Pfeiffer Syndrome

Pfeiffer syndrome (OMIM #101600) is an autosomal dominant disorder of craniosynostosis, broad thumbs, and great toes, and many cases are sporadic. Craniofacial features include synostosis of the coronal sutures producing brachycephaly, midface hypoplasia, and relative prognathism (Figure 144-3 and Figure 144-4). Hypertelorism, prominent/beaked nose, and high arched palate are also frequent findings. The hands and feet show a

**FIGURE 144-2** Jackson-Weiss syndrome. Variable craniosynostosis with brachycephaly (left) and acrocephaly (right) and large great toes and syndactyly. (From Jabs, E. W.; Li, X.; Scott, A. F., et al. *Jackson-Weiss and Crouzon Syndromes Are Allelic with Mutations in Fibroblast Growth Factor Receptor 2*. *Nat. Genet.* 1994, 8 (3), 275–279; Jackson, C. E.; Weiss, L.; Reynolds, W. A., et al. *Craniosynostosis, Midfacial Hypoplasia and Foot Abnormalities: An Autosomal Dominant Phenotype in a Large Amish Kindred*. *J. Pediatr.* 1976, 88 (6), 963–968.)

characteristic pattern of malformation (see [Figure 144-3](#)). Brachydactyly is common, and due to a shortening of (and in some cases, to a complete absence of) the middle phalanx. Thumbs and great toes are broad, and often show a varus deformity. There may be fusions between phalanges, or among various tarsal or carpal bones. Fusions of the proximal ends of metatarsals and metacarpals have also been described. Other bony abnormalities include fusion of cervical or lumbar vertebrae, radiohumeral and radioulnar synostosis (see [Figure 144-4](#)). Additional rare abnormalities associated with the Pfeiffer syndrome include ptosis, optic nerve hypoplasia, choanal atresia, preauricular tags, bifid uvula, supernumerary teeth, pyloric stenosis, and anteriorly placed anus (2).

As with several other dominant craniosynostoses, there is marked variability in expression. The wide spectrum

prompted Cohen (30) to propose a clinical classification of Pfeiffer syndrome into types I, II, and III. Type I is considered the “classic” Pfeiffer syndrome with the previously mentioned characteristics. This type may be inherited, and intelligence is generally normal. Type II is characterized by a cloverleaf (kleeblattschädel) skull deformity, the broad thumbs and great toes typical of Pfeiffer syndrome, and ankylosis of the elbows (see [Figure 144-4](#)). Type II is usually a sporadic occurrence with poor prognosis for intelligence and long-term survival. Type III is similar to type II without a cloverleaf skull. Proptosis is often marked. This type is also generally a sporadic occurrence within a family, and has a poor prognosis for survival and function. Types II and III are more likely to be associated with various internal anomalies as well, including abnormalities of the central nervous system. The classification is not absolute, and

**FIGURE 144-3** Pfeiffer syndrome type I. Brachycephaly, midface hypoplasia, mandibular prognathism, brachydactyly, broad thumbs that deviate radially, and short broad great toes with varus deformity and partial cutaneous syndactyly. (From Cohen, M. M., Jr. *An Etiologic and Nosologic Overview of Craniosynostosis Syndromes*. In *Malformation Syndromes, Birth Defects Original Article Series*; Bergsma, D., Eds.; 1975, 11 (2); pp. 137–189.)

there is overlap between the subtypes, yet was felt useful for classification and prognosis for an affected individual.

Pfeiffer syndrome is due to mutations in either fibroblast growth factor receptor 1 (*FGFR1*, OMIM \*136,350) or *FGFR2* (31). Patients with mild features of Pfeiffer syndrome have Type I and generally have *FGFR1* mutations. Patients with this syndrome can share identical *FGFR2* mutations with Crouzon and

Jackson–Weiss syndromes. Therefore, Pfeiffer syndrome is also considered to belong to the clinical spectrum of *FGFR2*-craniosynostosis syndromes.

#### 144.4.4 Apert Syndrome

Apert syndrome (OMIM #101200) is perhaps the most easily recognizable of the craniosynostosis syndromes.

**FIGURE 144-4** Pfeiffer syndrome type II. Brachyurricephaly, ocular proptosis, hypertelorism, depressed nasal bridge, midface hypoplasia, and low-set posterior rotated ears. Radiographs show mild cloverleaf skull deformity, increased digital markings, and radioulnar synostosis. (From Okajima, K.; Robinson, L. K.; Hart, M. A., et al. *Ocular Anterior Chamber Dysgenesis in Craniosynostosis Syndromes with a Fibroblast Growth Factor Receptor 2 Mutation*. *Am. J. Med. Genet.* 1999, 85 (2), 160–170.)

In addition to craniosynostosis and typical facial features, the hands and feet are characterized by a ‘mitten type’ syndactyly of the digits (Figure 144-5). Apert syndrome is also more likely to be associated with internal organ and central nervous system abnormalities as well as mental impairment. This syndrome is rare and occurs less than 1 in 65,000 births. Most cases are sporadic and only a few familial cases of autosomal dominant inheritance have been documented.

The pathogenesis of the craniosynostosis in Apert syndrome is somewhat unique. While the coronal sutures are typically fused at the time of birth, the sagittal suture generally does not form at all. Instead, there is typically a wide-open gap along the top of the skull at birth beginning at the glabella. Over the first 2–4 years of life, this gap is filled in by bony islands that eventually coalesce to form an intact calvarium. However, no sagittal or metopic suture is ever formed to allow for continued skull growth. This process has been described by Cohen and Kreiborg (32) as sutural agenesis, as opposed to

craniosynostosis in the sagittal region. Due to the large congenital “pressure valve” afforded by the gap in the bones, it is rare for an Apert syndrome patient to have difficulty with increased intracranial pressure in the first few years of life. However, the incidence of mental deficiency is still higher in these patients, due to a higher frequency of central nervous system defects.

The brain is typically megalencephalic, and the shape is also affected by the skull abnormalities. Due to the constriction of the area behind the fused coronal sutures, the developing brain is forced to grow upward and bulge forward, where the bony gap affords more room. This may lead to an appearance similar to that seen with an encephalocele. Other primary central nervous system defects include absent or abnormal corpus callosum, gyral abnormalities, white matter hypoplasia, heterotopic gray matter, and limbic structure defects (33). These primary abnormalities are likely to contribute to the finding that early surgical intervention does not appear to significantly improve intellectual outcome (34).

The facial appearance of an Apert syndrome patient is characterized by the high and prominent forehead, midface hypoplasia giving the appearance of prognathism, and a prominent, beaked nose (see Figure 144-5). There may be horizontal grooves over the supraorbital ridges in infancy that tend to disappear with age. The palate is typically high arched, and quite narrow, giving a “Byzantine arch” appearance. Crowding of the dentition is common. Of all the features of Apert syndrome, it is clearly the hands and feet that are most characteristic. There is severe and symmetric syndactyly of the digits, which at a minimum involves the second through the fourth fingers and toes, and may or may not involve the first and/or fifth digits as well. Nails may be distinct or continuous over several digits (see Figure 144-5).

Apert syndrome is also associated with an increased incidence of internal organ malformations, most commonly in the cardiovascular system (10%) and genitourinary system (9.6%). A smaller percentage was found to have respiratory and gastrointestinal malformations (each at 1.5%) (35). Certain dermatological conditions, such as hyperhidrosis, oily skin, and acneiform lesions are frequent in Apert syndrome. Acne is not only found on the face, but commonly extends to the arms, chest, and back (36).

Ninety-nine percent of Apert syndrome patients have either of two mutations, Ser252Trp or Pro253Arg, in FGFR2 (37).

#### 144.4.5 Muenke Syndrome

This craniosynostosis syndrome is defined by a Pro250Arg mutation in FGFR3, rather than a distinct phenotype (OMIM #602849) (7). The birth prevalence of this condition has been estimated to be one in 30,000 and may account for as much as 5% of all craniosynostosis cases (38). The associated clinical findings are highly variable,

**FIGURE 144-5** Apert syndrome. High prominent forehead, downslanting palpebral fissures, midface hypoplasia, and mitten type syndactyly of digits and severe syndactyly of toes. (From Lessard, M.-L.; Mulliken, J. B. *Major Craniofacial Anomalies. In Congenital Anomalies of the Ear, Nose and Throat, 1st ed.*; Tewfik, T. L., der Kaloustian, V. M., Eds.; Oxford University Press: Oxford, 1997; pp 307; Mann, T. P., Ed. *Colour Atlas of Paediatric Facial Diagnosis*; Kluwer Academic Publishers: London, 1989; pp 88.)

**FIGURE 144-6** Muenke syndrome. Brachycephaly, ptosis and downslanting palpebral fissures (left), mild ocular proptosis, hypertelorism, and prognathism (right). (From Paznekas, W. A.; Cunningham, M. L.; Howard, T. D., et al. *Genetic Heterogeneity of Saethre–Chotzen Syndrome, due to TWIST1 and FGFR Mutations*. *Am. J. Hum. Genet.* 1998, 62 (6), 1370–1380.)

with bicoronal or unicoronal synostosis, midface hypoplasia, downslanting palpebral fissures, and ptosis (Figure 144-6). Some patients with this mutation have a Crouzon-like, Pfeiffer-like, Jackson–Weiss-like, or Saethre–Chotzen-like phenotype. Large craniosynostosis families have been described with variable craniofacial morphology, including severe pancraniosynostosis (39–41). One such family has been referred to as having “Craniosynostosis, Adelaide type” (OMIM %600593). Other patients have isolated or non-syndromic craniosynostosis and still others have only macrocephaly or even a normal cranium. Developmental

delay and hand and foot anomalies are seen in some individuals. Radiographs can detect brachydactyly, distal and middle phalangeal hypoplasia, thimble-like middle phalanges, coned epiphyses, carpal bone malsegmentation, hallux valgus, and tarsal, calcaneal and navicular fusions. Although the phenotypic spectrum is highly variable, coronal craniosynostosis with brachydactyly and carpal/tarsal coalition have been suggested as the most characteristic features associated with this mutation (42). Patients also show significant, but incompletely penetrant and predominantly low frequency, sensorineural hearing loss (43).

### 144.4.6 Crouzonodermoskeletal Syndrome

There are patients who have features that resemble Crouzon syndrome, but also have a dermatological disorder of acanthosis nigricans and melanocytic nevi (OMIM #612247, Crouzon syndrome and acanthosis nigricans) (44) (Figure 144-7). The association of these skeletal and skin findings breeds true as a distinct autosomal dominant condition (45). Isolated acanthosis nigricans is characterized by verrucous hyperplasia of the skin and is usually found in flexural areas, but in this craniosynostosis condition it is present in the perioral, periorbital, and nasolabial areas as well as the neck, axillae, chest, breast, and abdomen. Additional findings include female preponderance, late childhood onset of dermatological features, severe choanal atresia, hydrocephalus, and cementomas of the jaw. Vertebral anomalies and conductive hearing loss are present with less frequency than in classic cases of Crouzon syndrome (46). Subtle forms of skeletal dysplasia associated with achondroplasia (OMIM #100800), the most common form of *FGFR3*-related short stature, such as brachydactyly and widening of the interpediculate distances of the spine, have been found in Crouzonodermoskeletal syndrome patients (47).

These phenotypic findings are consistent with different functional changes at the same transmembrane domain of *FGFR3* due to the Ala391Glu mutation in Crouzonodermoskeletal syndrome and the common Gly380Arg mutation in achondroplasia.

### 144.4.7 Beare–Stevenson Cutis Gyrata Syndrome

Beare–Stevenson cutis gyrata syndrome (OMIM #123790) is a rare condition with less than 20 reported patients (48). These sporadic cases are associated with

advanced paternal age, and therefore presumed and later proven through molecular studies to be heterozygous for autosomal mutations. The syndrome is marked by furrowed skin (*cutis gyrata*), acanthosis nigricans, craniosynostosis with craniofacial dysmorphism, digital anomalies, umbilical and anogenital anomalies, and early death (Figure 144-8). The *cutis gyrata* presents with fine ribbing and deep folds on the scalp, forehead, face, neck, chest, palms, soles, preauricular region, and perianal/genital region. The craniofacial features are similar to other craniosynostosis syndromes with midface hypoplasia, ocular hypertelorism and proptosis, choanal atresia, and palatal anomalies. In severe cases, a cloverleaf skull deformity may be present. A prominent umbilical stump can be noted at birth and is characteristic of this condition.

Beare–Stevenson syndrome is caused by missense mutations in *FGFR2*.

### 144.4.8 Osteoglophonic Dysplasia

Osteoglophonic dysplasia (OMIM #166250, Fairbank–Keats syndrome) is a rare, autosomal dominant skeletal dysplasia also associated with advanced paternal age. The major features are craniosynostosis, unerupted teeth, platyspondyly with anterior projection, brachydactyly, and rhizomelic dwarfism (Figure 144-9). The craniofacial anomalies are similar to those of other craniosynostosis syndromes with frontal bossing, ocular proptosis, and maxillary hypoplasia. Its most characteristic features are multiple lucent metaphyseal defects for which the name of the dysplasia was derived from a Greek word meaning “hollowed out.” The bones have generalized osteoporosis and are susceptible to fractures. Patients have demonstrated renal phosphate wasting and osteomalacia (1,49).

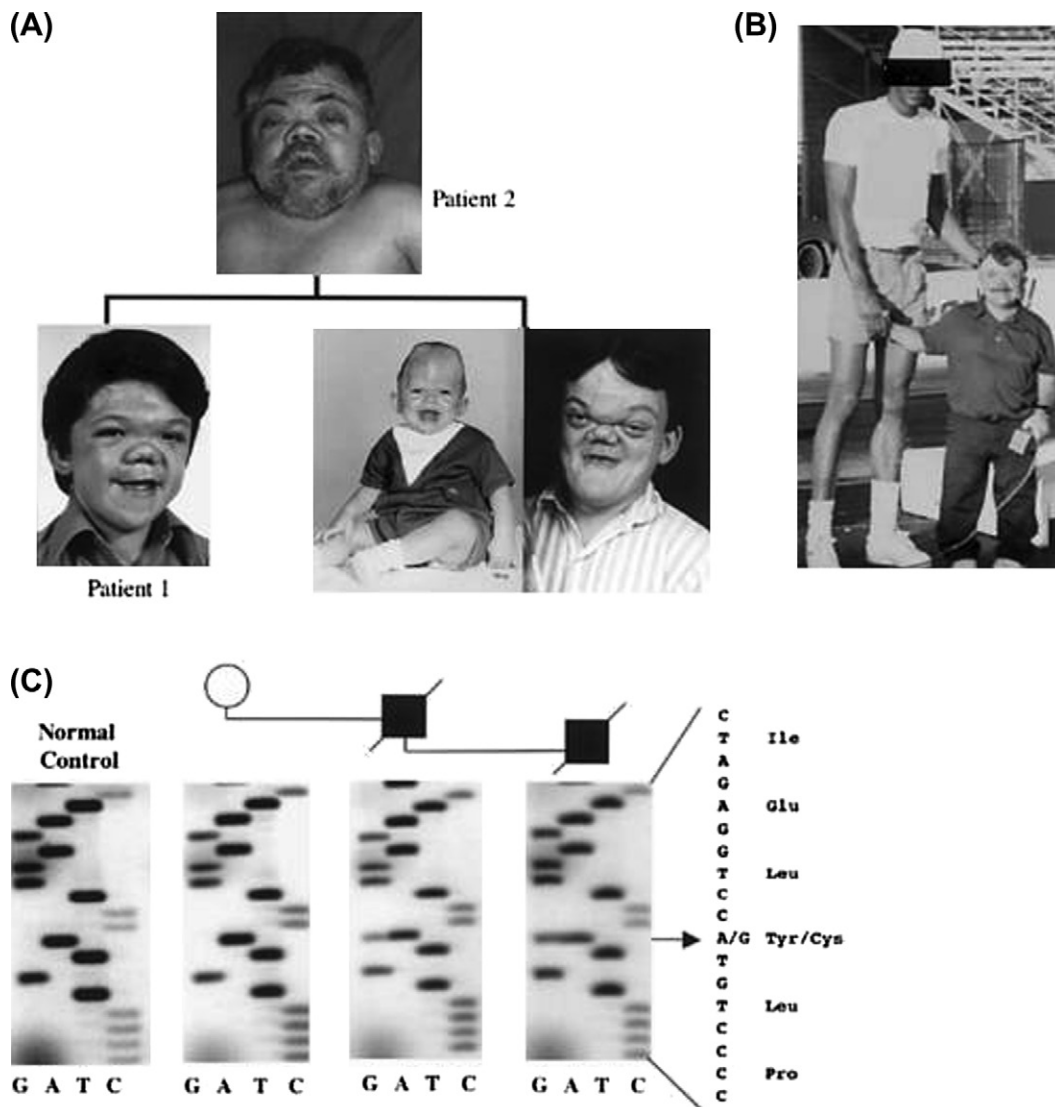

Osteoglophonic dysplasia is caused by missense mutations in *FGFR1*.

**FIGURE 144-7** Crouzonodermoskeletal syndrome. Ocular proptosis, midface hypoplasia, and hyperpigmentation and thickening of the neck. (From Meyers, G. A.; Orlow, S. J.; Munro, I. R., et al. *Fibroblast Growth Factor Receptor 3 (FGFR3) Transmembrane Mutation in Crouzon Syndrome with Acanthosis Nigricans*. *Nat. Genet.* 1995, 11 (4), 462–464.)

(From White, K. E.; Cabral, J. M.; Davis, S. I., et al. *Mutations that Cause Osteoglophonic Dysplasia Define Novel Roles for FGFR1 in Bone Elongation*. *Am. J. Hum. Genet.* 2005, 76 (2), 361–367.)

### 144.4.9 Saethre–Chotzen Syndrome

Saethre–Chotzen syndrome (OMIM #101400) is a common autosomal dominant, craniosynostosis condition. In general, however, the features are most often mild, and individuals only rarely require surgical intervention to address the cranial shape. It is felt to occur at a greater frequency than the other dominant craniosynostosis syndromes, and due to its milder nature, is likely to be under-diagnosed.

As craniosynostosis is not a constant feature, there is a wide variation in the appearance of affected individuals (50). Early closure may affect the various sutures, producing brachycephaly, acrocephaly, or trigonocephaly. The degree of sutural synostosis often differs between the right and left sides, producing both plagiocephaly and

facial asymmetry. In some cases, the fontanels may be late in closing, and there may be persistent parietal foramina. In addition to the asymmetry, the most common facial features are ptosis, a low frontal hairline, and ear abnormalities (Figure 144-10). Specifically, the ears tend to be small, and posteriorly rotated. The crura are often prominent. There is an increased incidence of hearing loss.

Hand and foot abnormalities are less dramatic than in other related syndromes. Often, there is brachydactyly with partial cutaneous syndactyly. Most often, the syndactyly occurs between the second and third fingers or toes, although other digits have also been reported to be affected occasionally. Bifid halluces or duplication of the large toe in association with features of Saethre–Chotzen syndrome had been designated as Robinow–Sorauf syndrome (OMIM #180570). Mutations in the same gene,

**FIGURE 144-10** Saethre–Chotzen syndrome. Facial asymmetry, midface hypoplasia, ptosis, and hypertelorism. (From Paznekas, W. A.; Cunningham, M. L.; Howard, T. D., et al. *Genetic Heterogeneity of Saethre–Chotzen Syndrome, due to TWIST1 and FGFR Mutations*. *Am. J. Hum. Genet.* 1998, 62 (6), 1370–1380.)

*TWIST1* (OMIM \*601622), have been found in both conditions, which suggest that Robinow–Sorauf represents cases of clinical variability in Saethre–Chotzen syndrome (51,52).

#### 144.4.10 Craniosynostosis, Boston-Type

Craniosynostosis, Boston-Type (OMIM #604757) is an autosomal dominant condition described in a single New England family (53). The affected family members have variable cranial morphology with craniosynostosis and the consistent finding of recession of the supra-orbital region in relation to the anterior surface of the cornea (Figure 144-11). Skull malformations included

forehead retrusion, frontal bossing, turribrachycephaly, and the cloverleaf skull anomaly. Most affected individuals were myopic or hyperopic. Several affected members suffered from severe headaches, and four had a seizure disorder. Intelligence was normal. No hand or foot abnormalities were noted on inspection, but radiographic examination demonstrated short first metatarsals in three of the four individuals evaluated. A cleft of the soft palate and a triphalangeal thumb were each noted in one member.

Craniosynostosis, Boston-Type is caused by a Pro-148His mutation in *MSX2* (OMIM \*123101) (54). It was the first mutation discovered to be associated with a craniosynostosis syndrome.

**FIGURE 144-11** Craniosynostosis, Boston-type with brachycephaly and frontal orbital recession (**top**; From Müller, U.; Warman, M. L.; Mulliken, J. B.; Weber, J. L. Assignment of a Gene Locus Involved in Craniosynostosis to Chromosome 5qter. *Hum. Mol. Genet.* 1993, 2 (2), 119–122.), and parietal foramina (**bottom**; From Wilkie, A. O. M.; Tang, Z.; Elanko, N., et al. Functional Haploinsufficiency of the Human Homeobox Gene *MSX2* Causes Defects in Skull Ossification. *Nat. Genet.* 2000, 24 (4), 387–390.) The two conditions: 1) brachycephaly and frontal orbital recession 2) parietal foramina, are caused by *MSX2* gain and loss of function mutations, respectively.

**FIGURE 144-12** Craniofrontonasal syndrome. Hypertelorism, divergent squint, central nasal groove (**left**, From Twigg, S. R.; Kan, R.; Babbs, C., et al. *Mutations of Ephrin-B1 (EFNB1), a Marker of Tissue Boundary Formation, Cause Craniofrontonasal Syndrome*. Proc. Natl. Acad. Sci. U.S.A. 2004, 101 (23), 8652–8657.), and orbital asymmetry (**right**, From Wieland, I.; Jakubiczka, S.; Muschke, P., et al. *Mutations of the Ephrin-B1 Gene Cause Craniofrontonasal Syndrome*. Am. J. Hum. Genet. 2004, 74 (6), 1209–1215.)

#### 144.4.11 Craniofrontonasal Syndrome

Craniofrontonasal syndrome (OMIM #304110) describes a subgroup of patients with frontonasal dysplasia. This syndrome is an X-linked condition associated with unilateral or bilateral coronal synostosis (55). Affected females have a severe cranial defect with hypertelorism and a bifid nasal tip (Figure 144-12). Other midline abnormalities are present including anterior cranium bifidum, corpus callosum hypoplasia, cleft lip and palate, omphalocele, unilateral breast hypoplasia, and diaphragmatic and umbilical hernias. There can also be craniofacial asymmetry and other skeletal malformations. Extracranial features include sloped shoulders with dysplastic clavicles, pectus excavatum, mild cutaneous syndactyly, and characteristic longitudinal groove of the nails. Less commonly, duplication of the first digit, joint abnormalities, axillary pterygium, and asymmetric lower limb shortness are present. Paradoxically, obligate transmitting males with this X-linked condition are more mildly affected with only hypertelorism and cleft lip and palate.

Craniofrontonasal syndrome is due to loss of function mutations in the ephrin B1 gene (*EFNB1*, OMIM \*300035)(56).

#### 144.4.12 Baller–Gerold Syndrome

Baller–Gerold syndrome (OMIM #218600) is a rare condition involving craniosynostosis and radial ray defects (Figure 144-13). The coronal suture is most often affected, but synostosis of the lambdoid, metopic, and sagittal sutures have been reported as well (2,57). There is also variability in the radial ray defects, which may include hypoplasia or aplasia of the radii and/or thumbs. Other upper extremity abnormalities, such as a short and curved ulnar bone are common.

**FIGURE 144-13** Baller–Gerold syndrome. Craniosynostosis with metopic ridge and radial aplasia with shortened forearms. (From Gorlin, R. J.; Cohen, M. M., Jr.; Hennekam, R. C. M., Eds.; *In Syndromes with Craniosynostosis; Syndromes of the Head and Neck*, 4th ed.; 2001; Oxford University Press: Oxford; pp 654–703.)

A long list of associated anomalies other than those of the skull and upper limbs has been reported in patients with Baller–Gerold syndrome. These include congenital defects of the heart, kidneys and vertebrae. Anteriorly placed or imperforate anus has also been reported, as

**FIGURE 144-14** Antley-Bixler syndrome. Craniosynostosis, fixed elbow joint, clitoromegaly and hooded prepuce. (From Reardon, W.; Smith, A.; Honour, J. W., et al. Evidence for Digenic Inheritance in Some Cases of Antley-Bixler syndrome? *J. Med. Genet.* 2000, 37 (1), 26–32.)

have perineal and rectovaginal fistulae. Short stature is common, and individuals with both mental retardation and normal intelligence have been noted. Due to the presence of these multiple additional features, other genetic conditions must be considered in individuals with craniosynostosis and radial ray defects. These would include Saethre-Chotzen, VACTERL (Vertebral, Anal, Cardiac, TE fistula, Renal, Limb) association (OMIM #192350), Fanconi's anemia, Roberts phocomelia (OMIM #268300), Rothmund-Thompson (OMIM #268400), Holt-Oram (OMIM #142900) and Thrombocytopenia-Absent Radius (TAR, OMIM #274000) syndromes. Effort should be made to exclude each of these conditions before assigning a diagnosis of Baller-Gerold syndrome.

Baller-Gerold syndrome is due to heterozygous mutations in the *RECQL4* gene (OMIM \*603780), which codes for a DNA helicase protein and increases predisposition to cancers and premature aging (9). Baller-Gerold syndrome could be integrated in a clinical spectrum that encompasses Rothmund-Thomson and RAPADILINO (OMIM #266280; RAdial ray defect, PAtella hypoplasia and aplasia and cleft or high arched PAlate, DIarrhea and DIsllocated joints, Little size and LImb malformations, NOse slender and NOormal intelligence) syndromes that are associated with radial ray defects, but not craniosynostosis. All three conditions are allelic as they can be caused by mutations in the *RECQL4* (9). Baller-Gerold and Rothmund-Thomson syndromes have overlapping features of poikiloderma and anterior displacement of the anus, while all three conditions have facial dysmorphisms, patellar abnormalities, growth deficiency, and

gastrointestinal disturbances in common. A patient with Baller-Gerold and a rare midline NK/T lymphoma was reported to have two different truncating mutations in the *RECQL4* gene (58).

#### 144.4.13 Antley-Bixler Syndrome with Genital Abnormalities and Disordered Steroidogenesis (POR Syndrome, P450 Oxidoreductase)

Antley-Bixler syndrome (OMIM #207410) was first described in a child with “trapezoidocephaly” from coronal and lambdoid synostosis, midface hypoplasia, humeroradial synostosis, bowing of femora, fractures, and other abnormalities (59) (Figure 144-14). Most cases have also been sporadic. Affected individuals may have additional skeletal and visceral features such as ocular proptosis, dysplastic ears, depressed nasal bridge, choanal stenosis, camptodactyly, and malformations of the heart and kidney. Respiratory obstruction with early demise has been reported in about 55% of cases.

Patients with Antley-Bixler syndrome have been associated with heterozygous, missense mutations in *FGFR2* (60). Of interest, patients with these mutations have features similar to a severe form of Pfeiffer syndrome with elbow synostosis, but do not have urogenital problems or recessive mutations initially attributed to some cases also called Antley-Bixler syndrome. Chun et al. (60) and Reardon et al. (61) proposed that Antley-Bixler syndrome patients with ambiguous genitals may represent a digenic or distinct condition (see below).

**FIGURE 144-15** Carpenter syndrome. Metopic ridging and lateral bulge with multiple suture synostosis, broad thumbs and syndactyly, brachydactyly, clinodactyly, and polydactyly. (From Jenkins, D.; Seelow, D.; Jehee, F. S., et al. *RAB23 Mutations in Carpenter Syndrome Imply an Unexpected Role for Hedgehog Signaling in Cranial Suture Development and Obesity*. *Am. J. Hum. Genet.* 2007, 80, 1162–1170.)

Patients with autosomal recessive inheritance of skeletal features of Antley–Bixler syndrome, fractures, bowing of the femurs, and ambiguous genitalia such as vaginal atresia, fused labia minora, and hypoplastic labia majora in females (OMIM #201750, see Figure 144-14) were subsequently found to have biochemical abnormalities in steroidogenesis with decreased activities of 17- $\alpha$ -hydroxylase, 17,20-lyase, and 21-hydroxylase (61). Virilization of affected females occurs due to disturbed androgen metabolism (62). Patients can also have abnormalities in sterol metabolism with decreased activity of lanosterol 14 $\alpha$ -demethylase (63). Furthermore, offspring of mothers taking the antifungal agent, fluconazole (an inhibitor of lanosterol 14 $\alpha$ -demethylase), during early pregnancy have Antley–Bixler-like features (64). All of these enzymes require cytochrome P450 oxidoreductase, and the *POR* gene (OMIM \*124015) coding for this cofactor was found to contain homozygous or compound heterozygous mutations in patients now designated with POR syndrome (3).

#### 144.4.14 Carpenter Syndrome (Acrocephaly Type II)

Carpenter syndrome (OMIM #201000) is a rare disorder with craniosynostosis, obesity, polydactyly, and soft-tissue syndactyly (65). Multi-suture craniosynostosis and polysyndactyly are present in all patients described to date, and abnormal external genitalia occur in all males. It is unlike the other inherited craniosynostoses mentioned above in two aspects. First, it is an autosomal recessive condition and secondly, the synostosis involves the midline metopic and sagittal sutures as well as the coronal sutures (Figure 144-15). Other characteristics include brachydactyly with shortening or absence of the middle phalanges, molar agenesis, genu valgum, hypogenitalism, congenital cardiac defects, umbilical hernia, and learning disability.

Carpenter syndrome is caused by mutation in the *RAB23* gene (OMIM \*606144), which encodes a member of the RAB guanosine triphosphatase (GTPase) family of vesicle transport proteins, and acts as a negative regulator of hedgehog signaling which is known to be involved in craniofacial development of the midline (5).

#### 144.4.15 Craniosynostosis and Dental Anomalies Syndrome (CRSDA)

This rare autosomal recessive, craniosynostosis syndrome is also referred to as Kreiborg–Pakistani syndrome (OMIM #614188) as it was described in Pakistani and English families. Affected individuals have metopic, coronal, sagittal, and/or lambdoid sutures, papilledema, maxillary hypoplasia with class III malocclusion, and variable dental anomalies of delayed tooth eruption of the canine and premolars and as many as seven supernumerary teeth in the incisor, canine, and premolar regions (Figure 144-16). Variably present were features like Crouzon syndrome and short stature, abnormal cranial base angle, prominent ears, constricted nasopharynx, broad first toes, hallux valgus, mild 2–3 toe syndactyly, clinodactyly, short phalanges, and dysplastic fingernails.

Interleukin 11 receptor, alpha (*IL11RA*, OMIM \*600939) gene mutations were identified using homozygosity mapping in three consanguineous families (8).

### 144.5 GENES RESPONSIBLE FOR CRANIOSYNOSTOSIS

#### 144.5.1 Fibroblast Growth Factor Receptors

**144.5.1.1 Biology of FGFRs.** The *FGFR* genes code for a family of proteins consisting of an extracellular

**FIGURE 144-16** CRSDA syndrome. Turribrachycephaly with exorbitism, trigonocephaly, and two supernumerary teeth indicated by arrows. (From Nieminen, P.; Morgan, N. V.; Fenwick, A. L. *Inactivation of IL11 Signaling Causes Craniosynostosis, Delayed Tooth Eruption, and Supernumerary Teeth*. *Am. J. Hum. Genet.* 2011, 89, 67–81.)

domain with three immunoglobulin-like domains (IgI, IgII, and IgIII), a transmembrane domain, and an intracellular domain with tyrosine kinase activity (66,67) (Figure 144-17). The protein conformation of the immunoglobulin-like domains is in part dependent on disulfide bonds, which form between cysteine residues (68). Immunoglobulin-like domains II and III (IgII and IgIII) are sufficient for ligand binding. In humans there are four known receptors and multiple alternative isoforms. Each receptor and each of its isoforms has its specific spatiotemporal pattern of expression during development.

Fibroblast growth factors (FGFs) act as ligands to these receptors (69,70). In humans there are 22 known FGFs, and each of these is expressed in a specific spatiotemporal pattern. These ligands bind to the receptors with differing affinity and specificity and induce the FGFRs to homodimerize or heterodimerize. FGFs are monomeric and are unable to activate FGFRs without heparan sulfate-containing proteoglycans (71). Formation of this complex results in transautophosphorylation of the receptor's intracellular tyrosine residues, which then stimulate the intrinsic catalytic activity of the receptors and recruit sites for downstream signaling proteins involved in distinct developmental pathways, such as MAPK, PLC $\gamma$ 1, and PI3K (72–74).

The expression of FGFRs 1–3 during calvarial ossification provides insight into the pathogenesis of craniosynostosis syndromes caused by mutations in these receptors. Before the ossification stage of human skull

development, FGFR1 is expressed in the head mesenchyme; FGFR2 is strongly expressed in the epidermis and the prebone mesenchyme condensations and the FGFR3 IIIc isoform is found at low levels in the epidermis and basal head mesenchyme (75,76). During membranous ossification of the skull vault, FGFR1 and FGFR2 and to a lesser extent FGFR3 are expressed in the prebone mesenchyme, prior to osteoblastic secretion of osteoid, around the mineralized bone. When sutures appear in the periphery of the ossification centers, high levels of FGFR1 and FGFR2 and low levels of FGFR3 IIIc are present at the osteogenic front of sutures in the prebone mesenchyme, osteoid, and periphery of the bone trabeculae. Expression of the mouse homolog of FGFR4 has been noted in the developing calvaria (76).

**144.5.1.2 FGFR Mutations.** More than 100 different mutations in FGFR1, FGFR2, and FGFR3 have been found in more than 1000 reported cases of Crouzon, Jackson–Weiss, Pfeiffer, Apert and other craniosynostosis syndromes usually involving the coronal suture (77–80). FGFR mutations have been identified in at least nine different craniosynostosis syndromes. There is more than one mutation for each FGFR–craniosynostosis syndrome, except Muenke and Crouzonodermoskeletal syndromes. Both Crouzon and Pfeiffer syndromes are associated with more than 50 different mutations.

To date all of the FGFR mutations that have been identified occur in FGFR2 with the exception of some occurring in FGFR3 and FGFR1. Most FGFR2 mutations occur in the extracellular domain, primarily in the

**FIGURE 144-17** Schematic protein diagrams. FGFR has an extracellular domain composed of three immunoglobulin-like domains (I, II, III) with disulfide bonds (S-S) and heparin binding sequence of heparan sulfate-containing proteoglycans binding domain (gray box), transmembrane domain (TM), and intracellular split tyrosine kinase domain (two rectangular boxes). The second half of IgIII is coded by a variably spliced exon (thickened portion of IgIII). TWIST1 has a DNA binding domain and helix-loop-helix region. The MSX2 homeodomain is composed of a flexible N-terminal extension followed by helices I, II, and III. EFNB1 has an extracellular domain composed of a signal peptide (SP) and ephrin domain, TM, and intracellular tyrosine residues and PDZ domain. RECQL4 has a helicase domain. POR has an electron donating flavin mononucleotide

IgII and IgIII domains coded by exons IIIa (also referred to as exon 8 and exon U) and IIIc (exon 10 and exon D). The recurrent mutations in these domains occur at amino acid residues Ser252, Pro253, Cys278, and Cys342, and account for more than 80% of all cases. No FGFR4 mutations have been detected in association with craniosynostosis.

FGFR mutations are usually amino acid substitutions. Many of these mutations replace or introduce a cysteine residue, resulting in aberrant disulfide bonds and alteration in the protein conformation of the ligand-binding region of IgII and IgIII. Identical missense mutations coding for FGFR1 Pro252Arg, FGFR2 Pro253Arg and FGFR3 Pro250Arg paralogs are observed in three different craniosynostosis conditions (81). There are some splicing mutations, small insertions, and deletions that are in-frame.

**144.5.1.3 FGFR In Vitro and Animal Models.** The mechanism by which FGFR2 mutations cause craniosynostosis is gain of function, and it has been studied extensively by microinjection of mutant FGFR2 mRNA in *Xenopus* oocytes/embryos or transfection of mammalian cells. The data show that some FGFR2 mutations cause ligand-independent constitutive activation by creating unpaired cysteine residues participating in intermolecular disulfide bonding (82,83). Other mutations, involving amino acid residues with side chains such as glutamic acid, aspartic acid and glutamine, create ligand-independent hydrogen-bonded FGFR dimers (84). A change in conformation in the kinase activation loop has been suggested to result in increased tyrosine kinase activity. The two Apert syndrome mutations, FGFR2 Ser252Trp and Pro253Arg, have been demonstrated to cause loss of ligand specificity and retained ligand dependence for receptor activation (85). An interesting animal model supports these findings. The model is a heterozygous mutant mouse, *Bey*<sup>+/-</sup>, with features that resemble Crouzon syndrome (86). The mice were created by retroviral insertional mutagenesis of ES cells, and the insertion was found in the intragenic region between *Fgf3* and *Fgf4*. The transcript analysis demonstrated that the expression of both FGF ligands is increased in the cranial sutures of the *Bey* mice and most likely causes secondary receptor overactivation. The various means by which the gain of function mutant mechanism is mediated for each of the different mutant receptors may in part explain the phenotypic variability.

Transgenic Crouzon syndrome *Fgfr2c*<sup>C342Y/+</sup> mice, having a mutation analogous to a common one found in patients, developed the typical characteristics of rounded calvaria, proptotic eyes, and shortened midface (87).

domain (FMN), flavin adenine dinucleotide domains (FAD), and nicotinamide adenine dinucleotide phosphate (NADPH) binding domain. RAB23 has GTP binding sites, switch domains, and prenylation signal. IL11RA has an SP, immunoglobulin-like domain, fibronectin-like III domains, and transmembrane.

Fusion of the coronal sutures occurred bilaterally with decreased cell proliferation and enhanced differentiation of osteoprogenitor cells. Transgenic Apert syndrome *Fgfr2*<sup>S252W/+</sup> and *Fgfr2*<sup>P253R/+</sup> mouse models have premature fusion of the coronal suture resulting from decreased proliferation, abnormal and increased differentiation, and accelerated bone formation at late embryonic stages as compared to controls. Along with the abnormal osteogenic process, there is aberrant chondrogenesis in these mice, with the presence of ectopic cartilage in the developing middle suture of the skull and long bones as well as a cartilaginous tracheal sleeve also observed in humans (88,89). Downstream of FGFR2, the ERK1/2 and p38 signaling pathways have been found to be activated and in turn, small molecule inhibition of these pathways ameliorates the skull phenotype (88,90,91).

The mechanism of the FGFR1 Tyr372Cys mutation in osteoglophonic dysplasia has been shown to be ligand-independent activation (49). This is in contrast to loss of function, FGFR1 mutations in Kallmann syndrome 2 (OMIM #147950), an autosomal dominant condition without craniosynostosis and characterized by hypogonadism and anosmia (92). Of interest, the characteristic features of osteoglophonic dysplasia overlap with those of FGFR2-craniosynostosis and FGFR3-short-stature conditions caused by activating mutations. The FGFR3-short-stature spectrum includes achondroplasia (OMIM #100800), hypochondroplasia (OMIM #146000), thanatophoric dysplasia types I and II (OMIM #187600, #187601), and SADDAN dysplasia (OMIM #134934.0015). Thanatophoric dysplasia type II is associated with a cloverleaf skull deformity, as well as severe dwarfism and typically the FGFR3 Lys650Glu mutation in the intracellular tyrosine kinase domain.

**144.5.1.4 Phenotype–FGFR Genotype Observations.** Some phenotype–genotype correlations have been delineated and therefore are useful for prenatal and postnatal diagnosis (Table 144-1). The most consistent correlation is the presence of either the FGFR2 Ser252Trp or Pro253Arg mutations in the linker region between IgII and IgIII and the clinically distinct Apert syndrome phenotype (37,93). These two mutations account for more than 99% of more than 400 cases of Apert syndrome reported in the literature. The Ser252Trp mutation is present in the majority (67%) of cases. Of interest, a single case of somatic mutation of FGFR2 Ser252Trp was described in a phenotypically normal male with severe acne; the mutation was found only in his affected skin and not his normal skin or blood (94). Severe acne can be a feature of Apert syndrome.

The FGFR1 Pro252Arg mutation, in the paralogous region of the less common FGFR2 Pro253Arg mutation of Apert syndrome, is associated with the Pfeiffer syndrome type I phenotype (31), whereas the more severe Pfeiffer syndrome types II and III are more often associated with FGFR2 mutations.

FGFR2 Ser351Cys or Trp290Cys mutations in the IgIII domain are found in severe cases of craniosynostosis with the clinical diagnosis of Pfeiffer syndrome that resemble Antley–Bixler syndrome, a diagnosis initially distinguished from the former by significant limb abnormalities of upper limb synostosis, lower limb bowing, and fractures (60,95).

The FGFR3 transmembrane mutation, Ala391Glu, is associated with Crouzonodermoskeletal syndrome (44). The presence of this FGFR3 mutation, rather than an FGFR2 mutation, predicts that a young patient will have acanthosis nigricans as well as craniosynostosis. FGFR2 juxta- or trans-membrane mutations, Ser372Cys and Tyr375Cys, are associated with Beare–Stevenson cutis gyrata syndrome (48). FGFR1 mutations Tyr372Cys, Cys379Arg, and Asn330Ile, in the analogous region of the IgIII domain cause osteoglophonic dysplasia (49).

Although traditionally many of the craniosynostosis syndromes have been considered clinically distinct, molecular data have shown that some are allelic conditions and can share identical mutations (79). Several FGFR2 mutations are present in patients with different clinical diagnoses. For example, FGFR2 Cys278Phe, Cys342Arg, and Cys342Ser mutations are each associated with Crouzon, Pfeiffer, and Jackson–Weiss syndromes. The FGFR2 Ser252Trp and the *FGFR2* IVS8-2A->G splicing mutation have been observed in cases with the diagnoses of Pfeiffer and Apert syndromes (96). FGFR2 Ser351Cys and Ala344Ala are seen in patients with atypical craniosynostosis cases and either Pfeiffer or Crouzon syndromes. Furthermore, the FGFR3 Pro250Arg mutation has been associated with several clinical diagnoses including Crouzon, Jackson–Weiss, Pfeiffer, Saethre–Chotzen, and unclassified syndromes. This specific mutation has also been identified in several affected individuals with non-syndromic unilateral coronal synostosis from a large prospective series, some of which were previously thought to be caused by intrauterine constraint (97). These conditions represent a spectrum of overlapping phenotypes caused by human FGFR2 and FGFR3 mutations and are now considered FGFR-related craniosynostosis syndromes. Furthermore, the fact that identical FGFR mutations may or may not result in craniofacial or other anomalies suggests that other genetic or stochastic factors modulate the effects of aberrant FGFR signaling on craniofacial, as well as limb and skin development.

Curiously, mutant FGFRs and their inappropriate expression in tumor cells of stem cell myeloproliferative disorder, multiple myeloma, and carcinomas such as breast, bladder, or cervix have been reported (98–101). Surprisingly none of the FGFR-craniosynostosis conditions caused by germline mutations are known to be associated with increased risk of tumors.

**144.5.1.5 Paternal Origin of Sporadic FGFR Mutations.** More than 20 autosomal dominant disorders including Crouzon, Apert, and Pfeiffer syndromes are

<sup>a</sup>For some disorders, there is no definitive information in the literature for each heading, to date. Either the most common mutations if there are multiple mutations associated with mutations if there are only a few mutations associated with a condition are listed.

<sup>b</sup>There are also variations in the noncoding regions of these genes in non-syndromic sagittal synostosis and their significance are unknown.

associated with advanced paternal age (102,103). Of interest, paternal origin of *FGFR2* mutations was molecularly proven for more than 100 sporadic cases of Crouzon, Apert, Pfeiffer, and Muenke syndromes. At least eleven different *FGFR2* mutations (nine missense, two splicing mutations) in Crouzon and Pfeiffer syndromes (104), the two common *FGFR2* mutations, Ser252Trp and Pro253Arg, in Apert syndrome (105); and the *FGFR3* Pro250Arg mutation in Muenke syndrome (106) have been shown to occur exclusively in the paternally derived gene. No cases of de novo mutations of maternal origin have been identified for any of these conditions. It has been suggested that *FGFR* genes, specifically *FGFR2* and *FGFR3*, may be predisposed to the mutational events and that the high frequencies of mutations in several of these nucleotides (e.g. Apert syndrome Ser252Trp mutation) may be due to a selective advantage of the mutated germ cells. Studies on the frequency of mutations in the male germline all agree that the frequency of the mutations in sperm increases with age. These results suggest that older men may be at an increased risk for having children with these craniosynostosis conditions (102,107).

### 144.5.2 TWIST1

The *TWIST1* gene (OMIM \*601622) codes for a transcription factor with a basic DNA binding and helix-loop-helix domains (see Figure 144-17). It is expressed during embryonic mesodermal development of the head and limbs. Early in murine development it is present in the mesoderm outside the primitive streak (108), and later it is found in the somites, head mesenchyme, first aortic arches, second through fourth branchial arches, limb buds, and the mesenchyme beneath the epidermis (109). *Twist1* is expressed in the undifferentiated cells committed to muscle and cartilage development and in primary osteoblastic cells from the newborn murine calvaria (110). The expression of *Twist1* precedes that of *Fgfr* genes at the time of initiation of the coronal suture.

More than 20 Saethre–Chotzen syndrome cases are associated with chromosome 7p15.3–p22 translocations, deletions, and other rearrangements outside the coding region of *TWIST1* (111,112). These chromosome 7 alterations are presumed to lead to loss of *TWIST1* function secondary to the loss of important regulatory regions or position effects. Partial duplication of chromosome 7p containing the *TWIST1* gene leads to delayed closure of a large anterior fontanelle, which is the opposite phenotype of craniosynostosis (113,114). This suggests that calvarial development is sensitive to *TWIST1* dosage.

More than 80 different *TWIST1* coding mutations have been identified in approximately 80% of patients with Saethre–Chotzen syndrome (51,111,115–119). The Tyr103STOP and 416–417dup21 are among the few recurrent mutations. The mutations can be missense, nonsense, duplication, deletion and insertions.

The latter types of mutations lead to a premature STOP codon and unstable mutant transcript by the mechanism of nonsense-mediated decay. Point mutations are also predicted to cause a loss of *TWIST1* function by altering the ability of the protein to dimerize or to bind to its DNA target(s). In vitro experiments have suggested that missense mutations involving the helical domains lead to loss of *TWIST1* heterodimerization with the E12 basic helix–loop–helix protein and altered ability of the *TWIST1* protein to localize in the nucleus (120).

Mice heterozygous for loss of the *Twist1* gene, with skull and limb anomalies similar to those in Saethre–Chotzen patients, further support the theory of haplo-insufficiency as being the mechanism of the *TWIST1* mutations. This loss of *TWIST1* function causes premature osteoblast differentiation (121). Furthermore, the dependence of cranial phenotype on genetic background in these heterozygous mice resembles the variable expressivity reported for Saethre–Chotzen syndrome (122). The significant interfamilial and intrafamilial variability of Saethre–Chotzen syndrome is found for patients with different *TWIST1* mutations as well as unrelated patients sharing identical mutations. Physical findings in patients with large gene deletions do not differ from those with point mutations. However, a correlation has been suggested between large deletions including *TWIST1* and developmental delay (111,112).

Patients with phenotypes that more closely resemble Saethre–Chotzen syndrome than other craniosynostosis conditions were found to have the *FGFR3* Pro250Arg mutation (40,50,81). The molecular data that mutations in different genes, such as *TWIST1* and *FGFRs* can cause very similar craniosynostosis phenotypes, suggest that these genes are involved in the same molecular developmental pathway. In fact, mice heterozygous for the loss of *Twist1* demonstrated ectopic expression of *FGFR2* in the midsutural mesenchyme of the developing sagittal suture of the skull (123). Therefore, based on both clinical and molecular data from humans with craniosynostosis and mice with loss of the *Twist1* gene, loss of function of *Twist1* leads to gain of function or activation of *FGFRs*. Thus it is not surprising that mutations in these genes both cause the common phenotype of craniosynostosis.

### 144.5.3 MSX2

The *MSX2* gene (OMIM \*123101) codes for a transcription factor protein containing a homeobox domain (see Figure 144-17). Murine *Msx2* is expressed in the neural crest derived from mesenchyme of first through fourth branchial arches, limb buds and calvaria. A mutation in the homeobox domain, Pro148His, was found in a large family with variable skull involvement ranging from fronto-orbital recession to cloverleaf deformity (54). This amino acid substitution is a gain of function mutation and confers enhanced DNA binding affinity (124).

A patient who was partially trisomic for chromosome 5q where the *MSX2* gene is located was reported to have craniosynostosis of the sagittal and lambdoid sutures, craniofacial abnormalities, cardiac defects, and growth and developmental delay (125). Mice with *Msx2* two-fold or less overexpression developed premature cranial suture fusion and ectopic bone formation (126). Mice with 13–22 copies of the transgene died around birth with severe craniofacial malformations, but with no evidence of craniosynostosis (127).

*Msx2*-deficient mice have defects of skull ossification and persistent calvarial foramen (128). This phenotype results from defective proliferation of osteoprogenitors at the osteogenic front during calvarial morphogenesis, and closely resembles that associated with human *MSX2* haploinsufficiency in the condition of parietal foramina (OMIM #168500) (129,130). These effects are opposite to those of the *MSX2* Pro148His homeodomain mutation, associated with craniosynostosis, demonstrating that the variation in skull phenotype is dose-dependent. Of interest, parietal foramina are genetically heterogeneous and can also be caused by loss of function mutations in the transcription factor, *ALX4* (OMIM #609597, \*605420; (131)). In mice, *Alx4* and *Msx2* are partially redundant in function (132). It is likely that *MSX2* and *ALX4* are components of the same molecular pathway of calvarial osteogenic proliferation and differentiation as *TWIST1* and *FGFRs*.

#### 144.5.4 Ephrin B1

Ephrin ligands and their tyrosine kinase receptor complexes play an important role in embryonic tissue morphogenesis through regulating cell shape and movement (133,134). The ligands themselves can also act as receptors, and in turn, the receptors can act as ligands so that bidirectional signaling is a mechanism by which ephrins control processes of cell–cell communication. There are two classes of ligand; ephrin A, which are anchored to the membrane by a glycosylphosphatidylinositol linkage, and ephrin B, which are transmembrane proteins. There are three members of the ephrin B protein family, each with an intracellular region of multiple tyrosine residues and a PDZ domain (see Figure 144-17). The ephrin B ligands play a role in the patterning of the developing skeleton, nervous system, intestine, and blood vessels. This transduction system is involved in neuronal growth and cell migration, mainly by acting as regulators through extracellular signal regulated kinase/mitogen-activated protein kinase (ERK/MAPK) and integrin cell surface interactions.

The mouse *Efnb1* gene is expressed in the frontonasal crest, and the human homolog was found to be mutated in craniofrontonasal syndrome patients (10,56,135). More than 80 different *ENFB1* mutations have been identified in cases of craniofrontonasal dysplasia (OMIM \*300035, #304110). Most are missense and others are nonsense,

frameshifts, or splicing mutations. Arg66STOP, Pro119His, and Gly151Ser are recurrent and an intragenic deletion has been detected. These mutations cause loss of function by affecting receptor–ligand interaction, oligomerization, and reverse signaling by the ligand.

Ephrin B1 knockout mice display a shortened skull, cleft palate, omphalocele, and malformations of the axial and appendicular skeleton similar to those found in craniofrontonasal syndrome patients (136). The mice have asymmetric attachment of ribs, lack of joints, and polydactyly, which are thought to be secondary to missing or ectopic segmentation of mesenchymal condensations during early skeletal development. The heterozygous female mice have additional features and lower viability compared to hemizygous males, similar to the paradoxical phenotypic observations in humans with this X-linked condition. No skewing of X-inactivation was observed in blood or cranial periosteum of patients (135) and no Y homolog was found to explain the severity in females. It has been postulated that “metabolic interference” or a disruptive effect of the mutant allele of the wildtype allele might be the mechanism by which females are more severely affected than males.

There is genetic evidence that Ephrins function together with *Twist1* and *Msx2* in boundary formation and the pathogenesis of coronal synostosis (137). In *Twist1*<sup>+/-</sup> mice with coronal synostosis, the frontal-parietal boundary is defective. Specifically, neural crest cells invade the undifferentiated mesoderm of the mutant coronal suture. This boundary defect is accompanied by an expansion in *Msx2* expression and reduction in ephrin-A4 distribution. Reduced dosage of *Msx2* in the *Twist1* mutant background restores the expression of ephrin-A4, rescues the suture boundary and inhibits craniosynostosis. Thus, mutations in the above genes are involved in the same molecular pathways in coronal synostosis.

#### 144.5.5 RECQL4

*RECQL4* is a member of the RecQ helicase family of proteins known to be involved in maintaining genome stability (138) (see Figure 144-17). There are at least three RECQ homologs, *RECQL2* (OMIM \*604611), *RECQL3* (OMIM \*604610), and *RECQL4*, known to be associated with five autosomal recessive disorders characterized by genomic instability and cancer predisposition including Werner (OMIM #277700), Bloom (OMIM #210900), Rothman–Thomson, RAPADILINO, and Baller–Gerold syndromes. Only one of the more than 24 reported Baller–Gerold syndrome patients was noted to have lymphoma (58).

It is known that *RECQL4* forms a stable complex with *UBR1* (OMIM \*605981) and *UBR2* (OMIM \*609134), which are ubiquitin ligases of the N-end rule pathway (139). Although *UBR1* and *UBR2* mediate polyubiquitylation and subsequent degradation of their

substrates, UBR1 and UBR2-bound RECQL4 were neither ubiquitinated in vivo nor degraded in HeLa cells. Further, the RECQL4-UBR1/2 complex was shown to have DNA-stimulated ATPase activity. Processing of aberrant DNA structures that arise during DNA replication and repair is a major role of ATP-dependent DNA helicase.

In Baller–Gerold syndrome patients, at least six mutations of RECQL4 have been identified with an Arg1021Trp substitution, splice site and frameshift mutations (9,140). Several knockout embryonic lethal and viable Recql4-mutant mouse models with exons 9–13 deleted have been generated. The latter mutant mice exhibited distinctive skin abnormality, birth defects of the skeletal system, genomic instability and increased cancer susceptibility on a sensitized genetic background, similar to Rothmund–Thomson syndrome (141). Cells from the mice had high frequencies of premature centromere separation and aneuploidy. Recql4 may have a role in sister chromatid cohesion leading to chromosomal instability, cancer predisposition and birth defects in the mutant mice. A mouse model with a Baller–Gerold specific mutation has not been generated to date.

### 144.5.6 P450 Oxidoreductase

P450 oxidoreductase (POR) is the obligatory flavoprotein intermediate that transfers electrons from reduced nicotinamide adenine dinucleotide phosphate (NADPH) to all microsomal cytochrome P450 enzymes (see Figure 144-17). The *POR* gene (OMIM \*124015) has a ubiquitous expression pattern. In humans, there are at least 57 genes for cytochrome P450 enzymes with 50 encoding microsomal P450s; including 20 genes encoding P450s involved in the biosynthesis of steroids, cholesterol, fatty acids, and eicosanoids. One would predict that loss of function mutations in P450 oxidoreductase would have significant multisystem consequences. In fact, POR knockout mice are embryonic lethal with neural tube, cardiac, eye, and limb abnormalities (142,143). However, in humans, POR recessive mutations have been identified with partial, combined deficiencies of two steroidogenic microsomal P450 enzymes: P450c17, which catalyzes steroid 17 $\alpha$ -hydroxylation and 17,20-lyase activity, and P450c21, which catalyzes steroid 21-hydroxylase activity; and deficiency of the sterol P450 enzyme, lanosterol 14 $\alpha$ -demethylase (3). Over 30 different mutations have been found in more than 40 cases (62,144–146). Most of the mutations are missense, but there are also nonsense, frameshift, splicing, small in-frame deletions and insertions. The Arg457His mutation is the most common in Japanese individuals because of a founder effect (145). The mutations that severely reduce the enzyme activity correlated most with the skeletal phenotype, while the milder mutations occurred in individuals with disorders of steroidogenesis, but normal skeletal development.

### 144.5.7 RAS-Associated Protein RAB23

RAB23 is a member of the RAB family of small guanine triphosphatases (GTPases) that regulate intracellular trafficking of membrane-associated proteins (OMIM \*606144) (147–149) (see Figure 144-17). Given the evidence that RAB23 regulates the hedgehog pathway, it is not surprising that some aspects of the phenotype of Carpenter syndrome resemble other human disorders associated with disturbed hedgehog signaling and midline structural abnormalities and limb defects. The most notably involved sutures are those in the midline, metopic and sagittal sutures. The combination of postaxial polysyndactyly of the hands and preaxial polysyndactyly of the feet is very similar to the pattern that occurs in Greig syndrome (OMIM #175700), which is due to haploinsufficiency of *GLI3*, a downstream component of the sonic hedgehog signaling pathway (150) and is consistent with decrease in *Gli3* repressor in *Rab23* mutant mouse embryos (151). The brachydactyly present in Carpenter syndrome, characterized by hypoplasia or absence of the middle phalanges, resembles brachydactyly type A1 (OMIM #112500), which is caused by heterozygous missense mutations in Indian hedgehog (152).

### 144.5.8 Interleukin 11 Receptor, Alpha

The ligand for the IL11RA receptor is interleukin-11. The binding of IL11 to IL11RA leads to the formation of a hexameric cell–surface complex of two ligands, two alpha-receptors, and two gp130 signaling co-receptors (beta receptors) (153) (see Figure 144-17). The formation of the signaling complex enables phosphorylation of the intracellular tyrosines of gp130 to trigger intracellular signal transduction, through either the *JAK/STAT1/3* or the *SHP2/MAPK/ERK* phosphorylation pathways (154,155). IL11 is widely expressed in mesenchymal and stromal cells and has been associated with diverse biological functions, including the regulation of bone formation and remodeling (156). The causative role of impaired IL11 signaling in the craniosynostosis phenotype of CRSDA patients was supported by phenotypic similarities between the human condition and *Il11ra* null mutant mice with the maxillary hypoplasia and class III malocclusion. Many missense mutations in CRSDA are located in the second fibronectin-type domain III (8).

## 144.6 OTHER SYNDROMES WITH CRANIOSYNOSTOSIS AND THEIR GENES

Disease genes have been identified for a few syndromes for which craniosynostosis is not a major feature. Greig cephalopolysyndactyly syndrome (OMIM #175700) is an autosomal dominant condition associated with preaxial and postaxial polydactyly of the hands and feet with variable syndactyly and hypertelorism. Craniosynostosis is observed in about 5% of cases. It is caused by

deletions of chromosome 7p13 region and loss of function mutations of *GLI3* (OMIM \*165240), a transcription regulator in the sonic hedgehog pathway during embryonic development. Mutations have been identified to be chromosomal translocations or large deletions, exonic deletions and duplications, small in-frame deletions, missense, and splicing mutations. Frameshift and nonsense mutations generally occur in the first and last thirds of the gene (157). The location of these mutations differs from those for the allelic condition, Pallister–Hall syndrome (OMIM #146510), which does not present with craniosynostosis. This latter condition is characterized by hypothalamic hamartoblastomas, craniofacial anomalies, bifid epiglottis, postaxial polydactyly, cardiac and renal defects and endocrine dysfunction. *GLI3* mutations are usually in the middle third of the gene for this syndrome. Other cases of Greig cephalopolysyndactyly with metopic and sagittal synostosis may resemble Carpenter syndrome and diagnostic testing for *GLI3* should be considered when no *RAB23* mutations are detected (158).

Alagille syndrome is an autosomal dominant condition with variable abnormalities of the liver, heart, skeleton, eyes and facial structures (OMIM #118450). A few cases have been reported with unilateral coronal craniosynostosis (159). Approximately 80% of patients with Alagille syndrome have mutations in the *JAGGED1* gene (OMIM \*601920). Jagged1 is a ligand in the Notch signaling pathway, which has been shown to regulate the formation of tissue boundaries. Jagged1 functions downstream of *Twist1* as an effector in the development of the coronal suture and in the formation of a boundary between osteogenic and non-osteogenic cells in mice (160).

Shprintzen–Goldberg craniosynostosis syndrome (SGS, OMIM #182212) is associated with craniosynostosis, exophthalmos, midface hypoplasia, arachnodactyly, camptodactyly, other connective tissue related problems and developmental delay (161). Furlong syndrome (OMIM #609192) is a similar Marfanoid disorder with craniosynostosis, which differs from SGS by the absence of mental retardation (162). It has been suggested that genetic variation in the fibrillin 1 (OMIM \*134797) and transforming growth factor beta-receptor 1 (OMIM \*190181) genes may play a role in the pathogenesis of craniosynostosis for these conditions.

C syndrome, also known as Opitz trigonocephaly syndrome (OMIM #211750), is associated with not only trigonocephaly, but also severe mental retardation, hypotonia, variable cardiac defects, redundant skin, abnormalities of joint and limbs, visceral anomalies, and dysmorphic facial features, including upslanted palpebral fissures, epicanthal folds, depressed nasal bridge, and low-set, posteriorly rotated ears (163). In a patient having C syndrome with a balanced chromosomal translocation t(3; 18), the *CD96* gene (OMIM \*606037) was disrupted at the 3q13.13 breakpoint (164). A Thr280Met mutation

in the *CD96* gene was found in one patient with severe features of the C syndrome phenotypic spectrum (165).

Several reports show an association of metopic synostosis or trigonocephaly with chromosomal abnormalities, more significantly with del(9)(p22p24) and del(11)(q23q24) (166). Deletions in these two chromosomal regions are associated with syndromic phenotypes and almost invariably include trigonocephaly. For the chromosome 9p region, more than 100 patients were assessed for copy number variations (CNVs). Five de novo CNVs involving *FREM1*, *FRAS1*-related extracellular matrix protein one gene (OMIM \*608944) were found and then three additional mutant alleles were identified by resequencing (167). Monosomy of chromosome 11q23 is associated not only with metopic synostosis, but also mental retardation, craniofacial anomalies, congenital heart defects, and blood dyscrasias and has been defined as Jacobsen syndrome (OMIM #147791). The haploinsufficiency of one gene in these regions could theoretically lead to either syndromic or non-syndromic cases of craniosynostosis. Less frequently, other chromosomal deletions such as those of 3q, 7p, 13q (1,168) and 22q11 (169) have also been associated with craniosynostosis.

Craniosynostosis may be observed in hypophosphatasia, particularly in the infantile type (OMIM #241500) if the affected child survives infancy. It is an autosomal recessive disorder of bone mineralization characterized by rachitic changes, failure to thrive, and seizures in infancy. Hypophosphatasia is caused by many different mutations in the alkaline phosphatase gene, *ALPL* (OMIM \*171760).

Craniosynostosis, anal anomalies, and porokeratosis syndrome (CAP syndrome, CDAGS; OMIM #603116) is another autosomal recessive condition of craniosynostosis, delayed closure of the fontanel, cranial defects, clavicular hypoplasia, anal and genitourinary malformations, and skin eruption. At least seven unrelated individuals have been reported, and it has been hypothesized that the gene defect in this condition causes abnormal regulation of multiple signaling pathways, including *RUNX2* (OMIM \*600211), during osteoblast differentiation and craniofacial morphogenesis (170).

### 144.7 NON-SYNDROMIC CRANIOSYNOSTOSES AND THEIR GENES

Little is known about the genetics of non-syndromic craniosynostosis (171). Initially a candidate gene approach was used. The *FGFR3* Pro250Arg (P250R) mutation is found in patients with non-syndromic coronal synostosis (97). Four to 12% of isolated unilateral and 25–40% of isolated bilateral coronal synostosis cases in clinic or hospital-based studies have the *FGFR3* P250R mutation (172,173). Cassileth et al. described poorer postoperative cranial morphology in patients with unicoronal synostosis and the *FGFR3* P250 mutation (174), and Arnaud et al. observed a trend for patients with bicoronal

synostosis and the FGFR3 P250 mutation to have revision surgery to correct cranial morphology more often than patients without the mutation (175). Thomas et al. conducted a retrospective study of patients with isolated coronal synostosis that were operated on at a single unit, and found that the FGFR3 P250R mutation was significantly associated with transcranial reoperation and specifically a 20.7% reoperation rate to relieve increased intracranial pressure (176). They also observed that cases with the mutation had early intervention to prevent excessive frontal bulging at around 6 months of age.

A FGFR2 Ala315Ser (A315S) mutation was reported in a patient with unicoronal synostosis and a birth history of breech presentation and skull compression (177). EFNA4 mutations were reported in a three patients with non-syndromic coronal synostosis (137). Mutations Ala186Thr, Ser188Leu, and Ser201Tyr in the TWIST1 Box domain were found in one case of isolated left coronal synostosis and two cases of isolated sagittal synostosis (178,179). In a family with autosomal dominant sagittal synostosis and metopic ridging, a FGFR3 Ala334Thr mutation was found (180). A FGFR1 Ile1300Trp mutation was found in a girl with non-syndromic metopic fusion who had two facial skin tags, but no other anomalies (181). A FGFR2 A315T mutation was reported in one case of non-syndromic sagittal synostosis (182).

Of note, a genome-wide association study was performed on non-syndromic sagittal craniosynostosis and identified risk loci on chromosomes 20 and 7 in the European American population (183). Preliminary results suggested the strongest associations were found with a  $p \leq 1.13 \times 10^{-14}$  (OR = 4.58) in the 3' UTR of BMP2 (OMIM \*112261) on chromosome 20 and  $p \leq 1.61 \times 10^{-10}$  (OR = 0.19) in an intron of BBS9 (OMIM \*607968) on chromosome 7. Furthermore, these significant associations were replicated in an independent American Caucasian population. Future studies will focus on these regions to identify disease-causing sequence variations and additional high-throughput technologies will be applied to discover disease genes for non-syndromic craniosynostosis.

## 144.8 EVALUATION OF CRANIOSYNOSTOSIS

### 144.8.1 Dysmorphology Examination

A multidisciplinary team approach is required for the evaluation and management of the patient's skeletal, audiological, ocular, oral, dental, respiratory, skin, and endocrine abnormalities (184). A genetic examination of a child with potential craniosynostosis or other craniofacial anomaly requires a thorough and detailed evaluation of appearance and structure. One must pay particular attention to cranial shape, symmetry, and facial features, as well as extracranial structures (such as hands and feet) that may also be involved in craniosynostosis syndromes.

The skull shape is best assessed from a “bird’s eye view,” usually best achieved with the examiner standing and the child on a seated parent’s lap. This will allow an overall assessment of the symmetry and shape of the cranium. In this way, one can look for areas of flattening or prominence of the skull. The head shape may be described as dolichocephalic, brachycephalic, or plagiocephalic. Additional features of skull shape can be assessed from a frontal view, such as a high or “tower” forehead referred to as acrocephaly, or whether the forehead is sloping backward or narrowed at the temples. Placement of the ears, whether at the same level, or one located more posteriorly than the other when seen from the top can also provide information as to the likelihood of a prematurely synostosed suture. Head circumference should also be obtained to document if there is restriction of normal skull growth.

Facial features are also very important in the evaluation of a child with craniosynostosis. Noting abnormalities of bony development, such as underdevelopment of the malar bones, shallow bony orbits leading to ocular proptosis, prognathism or retrognathism may be critical in helping to arrive at the correct diagnosis. Left/right asymmetry is a significant feature, and may involve either bony or soft tissues. For example, ptosis may affect one or both eyes, or both eyes to varying degrees, especially in Saethre–Chotzen syndrome. The shape of the nose should be noted as well, as a “beaked” appearance is common in several craniosynostosis disorders.

The oral cavity should be assessed for integrity and characteristics of the palate. Clefting is important, as is a particularly narrow and high arched (“Byzantine”) palate, as might be seen in the Apert syndrome. Dentition may be affected by the anatomy, such as missing teeth with alveolar clefting, or dental crowding in micrognathia. Ears should also be carefully described. The shape of the ear may be typical of a particular syndrome such as prominent ear crura in the Saethre–Chotzen syndrome.

Craniosynostosis syndromes may also involve dysmorphisms in extracranial regions. Most important, abnormalities of hands and feet can help to distinguish between different craniosynostosis syndromes, which may have similar facial appearances. Mitten-type syndactyly of all or almost all digits, as seen in the Apert syndrome is perhaps the most recognizable anomaly. Other syndromes may have more subtle and variable features. While bony or soft tissue fusions may be evident on physical examination, radiographs are helpful in assessing bony abnormalities not immediately apparent. Other organs should also be examined such as the heart and kidneys, which can be screened by ultrasonography. Evidence for genitalia abnormalities or endocrine dysfunction should be considered in making the diagnosis of POR syndrome.

Lastly, in performing a dysmorphology examination on a patient with possible syndromic craniosynostosis, the skin should be evaluated for texture or pigmentary

changes. Acanthosis nigricans, a darkened, raised, velvety textured patch is not only associated with Crouzon syndrome, it may help to identify the causative gene, *FGFR3* versus *FGFR2*, in that patient. Severe acneiform lesions on the arms or chest are often seen in the Apert syndrome. Cutis gyrata, an unusual, ridged texture to the skin is characteristic of the Beare–Stevenson cutis gyrata syndrome.

### 144.8.2 Radiographic Evaluation

If craniosynostosis is suspected on a clinical basis, the patient should be evaluated radiographically to assess the patency of the sutures. Plain skull films are often used as a screening device, but are not diagnostic. If the sutures are clearly seen to be open, the evaluation may end there. However, if the sutures are either felt to be synostosed or not well visualized, and then further evaluation is warranted.

A computed tomography (CT) scan is a more accurate way of assessing the patency of the sutures. This can be done in conjunction with a three-dimensional reconstruction of the individual images of the skull and skull base. This allows for a highly accurate assessment of sutural patency and bony contours. In addition, it allows the surgeon to “virtually reconstruct” the skull using the computer images. This exercise, when done preoperatively, gives the surgeon a better idea of the extent of skull remodeling that will be needed at the time of surgery.

Plain radiographs of the patient’s hands and feet as well as spine, hips, or long bones should also be considered at the time of workup, to potentially aid in the detection of subtle features and diagnosis of one of the many craniosynostosis syndromes.

### 144.8.3 Genetic Evaluation

A proper genetic evaluation of a patient with potential craniosynostosis begins with a thorough history. The patient’s mother should be questioned regarding any complications or medical conditions that may have impacted the pregnancy. Specific questioning should be directed at detecting any potential source of fetal crowding, such as uterine anomalies (large fibroids or bicornuate uterus) or a multiple gestation that may have led to compression of the baby’s head and secondary synostosis. History of medications such as anticonvulsant or retinoid use by the mother during pregnancy may be significant.

Family history is also quite important. Parents should be questioned regarding any congenital anomalies in family members. This includes not only abnormalities of head shape, but also visual problems, hearing loss, heart defects, digital anomalies, short stature, and early infant death. It is helpful if the parents are asked to bring family photos with them, so more subtle features of a mildly affected relative may be detected. Obviously, if

there is a documented family history of craniosynostosis, one would wish to know this information. However, this may not be volunteered by the parents, and should be specifically asked.

The patient’s medical history should be reviewed. Often, the patient is a young child with a relatively short medical history; yet important facts would include the length of gestation (premature infants often have a dolichocephalic shape to the skull), and the presence or absence of any medical conditions that may predispose to early sutural synostosis, such as hyperthyroidism. In young infants, sleeping position is also an important factor. As the medical profession has turned to promoting sleeping in a supine position for new babies, there has been a significant rise in referrals for, and evaluation of, positional plagiocephaly (185–187).

The physical examination, as detailed previously, is directed at identifying any abnormality of cranial shape as well as significant dysmorphic features that may be of diagnostic importance. As part of the evaluation, both parents should also be examined to rule out an inherited disorder of head shape and abnormalities of the hands and feet. The parent may thus be diagnosed with a mild form of craniosynostosis, whether syndromic or non-syndromic. An important distinction to be understood is that non-syndromic craniosynostosis does not mean noninherited. There are many families in which non-syndromic craniosynostosis is inherited in an autosomal dominant manner. This obviously will have important implications for the parents regarding their risk of having affected children. It is also important to inform parents that there can be phenotypic variability among affected family members with most autosomal dominant craniosynostosis conditions. Therefore, a mildly affected parent may have an offspring who is more or less severely affected.

### 144.8.4 Genetic Testing

If a craniosynostosis syndrome is suspected and a clinical diagnosis can be made, the risk for an affected parent to have an offspring with the same diagnosis is 50% for most of the craniosynostosis conditions discussed previously because they are autosomal dominant conditions. The exceptions are POR, Carpenter, or CRSDA syndromes and hypophosphatasia, which are autosomal recessive conditions and carry a recurrence risk of 25%. If both biological parents are unaffected and recessive conditions are excluded, their recurrence risk is less than 5%, which is an increased risk over that for the general population because of the possibility of gonadal mosaicism.

Chromosomal analysis or comparative genomic hybridization array may be useful in a child with craniosynostosis, other malformations, and development delay. Deletions at chromosome 9p22–p24 and 11q23–24 have been associated with trigonocephaly. In the case of Saethre–Chotzen patients with additional features and

developmental delay, a karyotype should be performed to rule out a chromosome 7p15.3–p22 rearrangement or deletion. Ninety percent of patients with a deletion involving the *TWIST1* gene have mental retardation.

To make a specific diagnosis or to predict the outcome of a pregnancy, gene testing can be ordered for a given syndrome (see Table 144-1). A single gene can be tested for some autosomal dominant conditions. *FGFR2* exons IIIa can be analyzed for the mutations that code for Ser252Trp and Pro253Arg and will be detected in 99% of Apert syndrome cases. *FGFR2* juxta-transmembrane mutations can be found with Beare–Stevenson cutis gyrata syndrome. A *FGFR3* mutation in the exon that codes for the juxta-transmembrane will be found in 100% of cases of Crouzonodermoskeletal syndrome. *FGFR1* can be tested for mutations in osteoglophonic dysplasia patients. *MSX2* Pro148His mutation can be tested for Craniosynostosis, Boston-Type. The coding region of the *EFNB1* gene can be screened for mutations that will be found in 87% of craniofrontonasal dysplasia patients.

More than one gene should be tested for in patients with the clinical diagnosis of Crouzon, Pfeiffer, Jackson–Weiss, Antley–Bixler, and Saethre–Chotzen syndromes, as they have significant overlapping clinical features and genetic heterogeneity. *FGFR2* exons IIIa and IIIc and *FGFR3* exon IIIa should be tested in patients that have features of Crouzon or Jackson–Weiss syndrome, and a mutation will be detected in more than 90% of cases. *FGFR1* exon IIIa (Pro252Arg), *FGFR2* exons IIIa and IIIc, and *FGFR3* exon IIIa (Pro250Arg) should be tested for patients with features of Pfeiffer syndrome, and a mutation will be detected in more than 85% of cases. Mutations in *FGFR2* exons IIIa and IIIc and the coding regions of the *POR* gene can be found in the majority of patients with features of Antley–Bixler syndrome. *POR* gene testing should be prioritized in cases with ambiguous genitalia and abnormalities of steroidogenesis.

Saethre–Chotzen syndrome patients should first be tested for *TWIST1*, then the *FGFR3* exon IIIa (Pro250Arg mutation). A microdeletion can be detected in about 11% of cases by dosage analysis using genotype markers, fluorescent in situ hybridization (FISH), or other dosage-detection methods such as real-time PCR, multiplex ligation-dependent probe amplification (MLPA), or comparative genomic hybridization (CGH) (111,157). Using this combination of genetic tools, more than 70%–80% of mutations can be detected in Saethre–Chotzen syndrome patients. Patients in whom the diagnosis of Baller–Gerold syndrome is possible should undergo *RECQL4* gene analysis, but may also require testing to rule out Fanconi’s anemia, Thrombocytopenia–Absent Radius, and Roberts syndrome or imaging studies for possible VACTERL.

To detect rare mutations in the spectrum of craniosynostosis syndrome above, one can screen *FGFR2* exons 3, 5, 11, and 14–17; and search for heterozygous gene

deletions (MLPA kit including *TWIST1*, *MSX2*, *ALX4*, *EFNB1*, and *RUNX2*) (188). Non-syndromic coronal craniosynostosis patients can be screened for the *FGFR3* exon IIIa for the Pro250Arg mutation and the *FGFR2*, *TWIST1*, and *EFNA4* genes, and non-syndromic sagittal synostosis may have *FGFR2* and *TWIST1* changes. Non-syndromic metopic synostosis patients can be screened for mutations in the *FGFR1* gene to detect the Ile300Trp mutation.

At one craniofacial unit, targeted molecular genetic and cytogenetic testing was performed on 326 children born from 1993 to 2002 who required surgery for craniosynostosis and were monitored until the end of 2007 (38). Eighty-four children were screened for pathological genetic alterations in *FGFR1*, 2, 3, *TWIST1*, *EFNB1* and *CGH*. Eighty-six percent had single-gene mutations and 14% chromosomal abnormalities. Genetic diagnoses were made for 21% of all craniosynostosis cases, and the *FGFR3* P250R mutation was the single most common mutation, accounting for 5% of all cases. Those with genetic diagnoses were associated with increased rates of many complications. Children with the clinical diagnosis of non-syndromic unicoronal or bicoronal synostosis were more likely to have a causative mutation than those with sagittal or metopic synostosis. Repeat craniofacial surgery was required for 58% of children with single-gene mutations and 17% of those with chromosomal abnormalities.

Gene testing is particularly useful in cases of prenatal diagnosis where ultrasound monitoring cannot detect subtle features associated with craniosynostosis syndromes. Postnatal diagnosis is important when the affected status of a relative is not clinically obvious. Testing offered to first-degree relatives can assess the risk to their offspring. Knowledge of whether a newborn will be affected with craniosynostosis and of known phenotype–genotype correlations will allow health care professionals to plan treatment, anticipate and potentially avoid complications of increased intracranial pressure, hydrocephalus, deafness, visual problems, cleft palate, choanal atresia, dental malocclusion, respiratory problems, dermatological disorders, psychosocial difficulties, and mental retardation in children with craniosynostosis.

### Biographies

**Ethylin Wang Jabs** is currently the Vice Chair and a Professor of the Department of Genetics and Genomic Sciences, Professor of Pediatrics, and Professor of Developmental and Regenerative Biology at Mount Sinai School of Medicine. She has an adjunct appointment as Professor of Pediatrics, Medicine, and Surgery at Johns Hopkins University. Dr Jabs is a member of the Society for Pediatric Research, American Association of Physicians, and the American Society for Clinical Investigation and is a medical advisory board member of The Smile Train and Moebius Syndrome Foundation. She served as President of the Society of Craniofacial Genetics. She has been on the editorial board of the *Journal of Craniofacial Genetics and Developmental Biology*, *Pediatric Research*, and *Genetics in Medicine*. Dr Jabs is a clinically active pediatric geneticist who is board certified in clinical genetics, clinical cytogenetics, and molecular genetics. The major research interests of the Jabs' laboratory include developmental genetics of craniofacial disorders. These studies are elucidating the pathogenetic mechanisms of mutations, signaling pathways involved in abnormal processes and phenotype-genotype correlations. Population association studies are being conducted on non-syndromic cleft lip with or without cleft palate and craniosynostosis. Based on these findings, therapeutic strategies are being tested in transgenic mouse models for craniosynostosis to ameliorate abnormal craniofacial morphology.

**Dr Amy Feldman Lewanda** is a pediatric medical geneticist at Children's National Medical Center in Washington, DC. After receiving her MD degree from the Mount Sinai School of Medicine in New York, NY, she completed an internship and residency in Pediatrics at Mount Sinai Hospital. This was followed by a fellowship in Medical Genetics at Johns Hopkins Hospital in Baltimore, MD. Her research focused on identifying genes responsible for craniosynostosis syndromes. After her fellowship, Dr Lewanda has been in clinical practice with a particular interest in craniofacial genetics, prenatal diagnosis, and congenital malformations.

## Abnormalities of Pigmentation

*Richard A Spritz*Human Medical Genetics and Genomics Program, University of Colorado School of Medicine,  
Aurora, CO, USA*Vincent J Hearing*

Laboratory of Cell Biology, National Cancer Institute, National Institutes of Health, Bethesda, MD, USA

This article is a revision of the previous edition article by Richard A King, William S Oetting, C Gail Summers, Donnel J Creel, and Vincent J Hearing, volume 3, pp 3380–3427, © 2007, Elsevier Inc.

**145.1 INTRODUCTION**

Because of their visually striking phenotypes, disorders of pigmentation were the first genetic diseases ever documented, with clinical descriptions in some cases dating back hundreds or even thousands of years. Similar phenotypes have been observed in many different mammalian species, and during the Victorian era the breeding of mice with interesting coat pigmentation patterns became a popular hobby, eventually forming the basis of one of the most important animal models of modern scientific research. With the rediscovery of Mendel's principles of genetics early in the twentieth century, albinism was one of the original diseases proposed by Garrod as an "Inborn Error of Metabolism" (1,2), and the inheritance of normal human pigmentary variation was one of the first traits studied, though with limited success.

The processes involved in regulating normal pigmentation (also termed melanogenesis) occur at many levels and are under complex control. Pigment cells, known as melanocytes, must develop and migrate to the correct tissue locations and have all the components needed to produce melanin in a specific subcellular organelle, known as the melanosome. These processes are under strict genetic control, with many gene loci involved. Variations in and interactions of many of those loci regulate constitutive levels of pigmentation, including skin, hair and eye color. Furthermore, pathological mutations in many of these same genes can more drastically affect pigmentation in humans, resulting in various pigmentary diseases which involve reduced pigmentation (hypopigmentation), increased pigmentation (hyperpigmentation), or abnormal pigmentary patterning.

In the mouse, over 370 loci are currently known to affect melanocyte development, migration, and melanogenesis (3–5), and over half of these genes have been

identified, as have their human homologs (<http://www.espcr.org/micemut/>; The Albinism Database, <http://www.cbc.umn.edu/tad/genes.htm>; The Human Gene Mutation Database, <http://www.hgmd.org>). The products of these genes include melanosomal enzymes, melanosomal structural proteins, and proteins that regulate gene expression in melanocytes, either as DNA-binding proteins or as members of signal transduction pathways (see Table 145-1).

Genetic disorders of pigmentation can be generally categorized as disorders of melanocyte development, differentiation, or migration; disorders of melanocyte function; disorders of melanosome biogenesis/transport; and disorders of melanocyte survival (for reviews, see References (6–9)). Disorders of melanocyte development, differentiation, or migration typically result in abnormal pigmentary patterning, with congenital patches of hypopigmented skin and overlying hair that largely lack melanocytes, such as in piebaldism or Waardenburg syndrome. Disorders of melanocyte function typically result in global hypopigmentation, with reduced melanin levels in the skin, hair, ear and eye. This may be due to the reduced ability of melanocytes to make melanin, such as in classical oculocutaneous albinism, or due to more complex defects of melanosomes as well as other organelles, such as in Hermansky–Pudlak syndrome, with consequent abnormalities of other organ systems, such as the thrombopoietic and immune systems. Disorders of melanocyte survival involve the abnormal destruction of functional melanocytes, such as in generalized vitiligo. Disorders of hyperpigmentation also occur, such as melasma and post-inflammatory pigmentation, which result in abnormal increases in levels of melanin that can be temporary or permanent. Recent work on these disorders has provided important insight into fundamental components that

TABLE 145-1 Genes and Diseases of Pigmentation

Gene	Human Disease	Inheritance	Murine Locus	Protein
<b>Disorders of melanocyte development, differentiation, or migration</b>				
<i>KIT</i>	Piebaldism	Dominant	Dominant white spotting ( <i>W</i> )	Receptor tyrosine kinase
<i>KITLG</i>	Familial Progressive Hyperpigmentation?	Dominant	Steel ( <i>Sf</i> )	KIT ligand
<i>PAX3</i>	Waardenburg syndrome types I,III	Dominant	Spotch ( <i>Sp</i> )	Transcription factor

regulate melanocyte functions, including development, proliferation, survival and differentiation.

This chapter describes our current understanding of mechanisms and genes involved in regulating the pigmentary system and disorders that result when their functions are disrupted (summarized in Table 145-1). Brief overviews of melanocyte biology and the biochemistry and genetics of melanogenesis are included, to provide a background for understanding the mechanisms involved in pigmentary disorders. Many of the genes discussed function at multiple levels (e.g., development, migration and differentiation), and in such cases the genes are summarized at first mention in this chapter.

## 145.2 THE PIGMENTARY SYSTEM

Melanocytes constitute only a minor subpopulation of cells in mammalian tissues, but they are the only cells that can produce the melanin needed to pigment the skin, hair and eyes (reviewed in References (10,11)). The melanin produced has a variety of important and distinctive functions:

1. As a cosmetic entity—participating in protective coloration and in sexual attraction within species
2. As a barrier protecting against ultraviolet (UV) radiation

3. As a potent scavenger of cytotoxic radicals and intermediates
4. As a participant in developmental processes—particularly relating to optic/neurologic development

Melanocytes that populate the skin (epidermis and hair bulbs) originate as melanocyte precursors (termed melanoblasts) in the neural crest during embryologic development (reviewed in References (12,13)). Melanocytes that reside in other locations, e.g., the choroid of the eye and the stria vascularis of the inner ear, also originate from the neural crest, whereas the retinal pigment epithelium (RPE) of the eye is of neuroectodermal origin. Melanoblasts migrate throughout the developing organism to their eventual destinations, then must stop migrating, survive, proliferate and differentiate into melanocytes. The melanin produced is a large pigmented biopolymer synthesized within specific unique subcellular organelles termed melanosomes. The melanins produced, and the melanosomes wherein they are deposited, can be of several types, with differing visible colors and presumably with distinct functional properties. The major classes of melanins are brown-black eumelanins and yellow-red pheomelanins. In the epidermis and hair bulbs, the visible colors produced also depend on transfer of pigment-bearing melanosomes from melanocytes to neighboring keratinocytes, where

they are further distributed in the upper layers of the epidermis and into hair shafts.

Mammalian pigmentation is regulated at many different levels and is influenced by many genes, either directly or indirectly. In mice, more than 700 different mutations have been identified that affect pigmentation, and these map to more than 370 distinct genetic loci (reviewed in References (3,14) and the curated Coat Color Genes website, <http://www.espcr.org/micemut/>). Many of these pigment-related genes have now been identified and are known to regulate human pigmentation as well, operating at the tissue, cellular, or subcellular level.

### 145.2.1 Development of Melanocytes

As noted above, in vertebrates, all melanocytes (except those in the RPE) originate from melanoblast precursors derived from the dorsal neural tube during embryonic development (reviewed in References (12,13)). For melanoblasts to reach their eventual destinations in the body, cues must be provided to initiate migration of these precursor cells from the neural tube along defined pathways. They must continue to migrate along those pathways to their targeted destinations, and then they must stop migrating and begin to transition into functional melanocytes (the latter process being termed specification). Each of those steps is under the control of many independent genetic and environmental factors, and the overall timing of these processes is critical for achieving the correct adult pigmentation patterns in a given individual of any species.

The genes that function at this level encode, among other things, transcription factors (e.g. *MITF*, *PAX3* and *SOX10*), receptors and their ligands (e.g. *EDNRB/EDN3* and *KIT/KITL*), and other factors important to the start/continue/stop signals for migration, specification, etc. (e.g. *ADAMTS20* and *SNAI2*). Mutations in these genes and/or disruptions of their functions may perturb normal development, leading to developmental diseases that affect pigmentation, and in many cases also affect other tissues that in some way depend on cells derived from the neural tube. Regarding pigmentation, these diseases typically involve white spotted areas where melanoblasts failed to populate (typically on the forehead and abdomen) that are congenital and relatively stable throughout life. Examples of such developmental diseases include Waardenburg Syndrome (WS), Hirschsprung's disease (HSCR) and Piebaldism (reviewed in References (9,12,13,15–19)). A summary of genes involved in melanoblast development, migration and specification, along with the functions of their encoded proteins and associated diseases (when known) is provided in Table 145-1.

### 145.2.2 Distribution and Survival of Melanocytes

The eventual distribution and survival of melanocytes in a given tissue such as the skin is an important factor in

determining the pigmented phenotype. Melanocytes in the eye are localized in the choroid, iris and retina, where they function essentially as a photoprotective barrier. Ocular melanocytes are relatively dormant, and their rates of melanin production are low following fetal development. Unlike other melanocytes, in ocular melanocytes pigment granules remain within the cells. In contrast, in follicular melanocytes (i.e., those within hair bulbs), melanosomes are transferred to evolving hair shafts, thus giving the hair visible color. As they age, hair bulb melanocytes often decrease or even cease production of pigment, resulting in the characteristic graying of hair associated with aging (5,20–22). Similarly, skin melanocytes reside stably at the dermal–epidermal border and proliferate extremely slowly, if at all. Their melanosomes are transferred to neighboring keratinocytes, the predominant cell type in the epidermis. Melanosomes transferred to keratinocytes are then processed, being further degraded and redistributed, in smaller pieces and/or in larger complexes that eventually result in visible skin color as the proliferative keratinocytes migrate towards the skin surface (23). The number of melanocytes per unit area in the skin is remarkably similar between races, and the phenotypic differences of skin colors, ranging from white to black, depend principally on the quantity and distribution of the melanin “packets” or dust in the keratinocytes near the skin surface rather than melanin within the melanocytes (reviewed in References (23–27)).

As discussed above, the appropriate distribution of melanocytes in the skin, hair, and eyes depends on proper development of melanoblasts during embryological development, their appropriate migration to distant sites in the developing organism, and their differentiation to functional melanocytes once in place. It has become clear that many of the pigment-specific genes are involved in regulating human pigmentation at multiple stages, and many of these same genes, when mutant, result in pigmentary disorders. To date, a large number pigment-related genes involved in melanocyte signaling events that regulate melanoblast distribution and survival have been identified, characterized, and associated with pigmentary diseases. These include many of the same genes discussed above that are involved in melanoblast development, such as piebaldism (*KIT*), WS (*PAX3*, *SOX10*, *MITF*, *SOX10*, *EDNRB*, *EDN3*), and Hirschsprung disease (*EDNRB* and *EDN3*).

Once melanoblasts have arrived at their final destinations in the tissues, they must survive and proliferate to populate the tissue to achieve the correct distribution and density required for normal function. A relatively large number of genes are involved in those processes, and their disruption can lead to decreased melanocyte function in the adult. Again, the genes involved in these processes encode, among other things, transcription factors (e.g. *MITF* and *FOXD3*), receptors and their ligands (e.g. *EDNRB/EDN3* and *KIT/KITLG*), and other factors important to the signals that regulate proliferation, survival, etc. (e.g. *BCL2* and *SEMA3C*). Many of these genes function at multiple stages, ranging from developmental processes (as noted

above) through differentiation processes (as discussed below). Regarding effects on pigmentation, mutations in those genes typically lead to hypopigmented areas where melanoblasts failed to differentiate or survive that are progressive; pigmentation may be normal at birth, but pigmentation abnormalities become more severe with age. Examples of such diseases include Vitiligo and Reticular pigmentosum (for reviews, see References (7,28–35)).

### 145.2.3 Differentiation and Function of Melanocytes

Many of the precursors and intermediates in the melanin biosynthetic pathway are cytotoxic quinones and derivatives, and that is probably a major reason why the biochemical machinery to produce melanin is confined within the membrane-bound melanosomes. Melanosomes are lysosome-related organelles (LROs), and many of their components are shared with other LROs (36–38). The specific structure and function of melanosomes relates to the specific expression of a limited number of melanosomal proteins that are produced only in melanocytes. Melanosomal biogenesis begins with the blebbing of membrane-bound vesicles from the smooth endoplasmic reticulum, initially containing only an amorphous matrix and termed stage I melanosomes. Stage I melanosomes do not contain any of the melanogenic enzymes required to produce melanin but do contain PMEL17 protein which is required to make the fibrillar matrix (36,39). Depending on the type of melanin to be produced, the melanosomes then reorganize from amorphous structures either into characteristic fibrillar patterns oriented along the longitudinal axes of the organelles (for eumelanin production) or into particulate spherical organelles (for pheomelanin production), at which time they are termed stage II melanosomes. Tyrosinase and other melanogenic determinants, such as the tyrosinase-related proteins (TYRP1 and DCT), are synthesized on ribosomes and are processed through the endoplasmic reticulum to the Golgi apparatus, where they are glycosylated en route to the active face of that network (reviewed in References (23,40)). They are then secreted within coated vesicles into the cytoplasmic milieu and are transported specifically to stage II melanosomes, where they fuse with its limiting membrane, with their catalytic domains facing inward, and active melanogenesis begins (stage III melanosomes). Fully pigmented stage IV melanosomes are filled with melanin, and no internal architecture remains visible.

Ultrastructural histochemistry has clearly demonstrated that tyrosinase is functionally competent while in transit through the Golgi apparatus and in coated vesicles, and it is not clear how melanogenesis is delayed *in vivo* until tyrosinase arrives at the melanosome (40,41). The mechanism involved is of great interest because it may play a role in some types of abnormal hypopigmentary conditions in which active tyrosinase is present yet no melanin is produced. Once melanogenesis has begun, the melanin produced is deposited in characteristic patterns within

melanosomes. If eumelanin is produced, it accumulates uniformly on internal fibers of melanosomes, and the opacity of the organelles gradually increases until eventually all substructure is obscured. If pheomelanin is produced, it accumulates in a heterogeneous fashion within particulate spherical melanosomes, which do not become fibrillar due to the lack of PMEL17 expression. Regardless of which type of melanin is produced, as melanosomes mature they steadily move away from the perinuclear region to the peripheral dendritic areas of melanocytes using the molecular motor machinery of melanocytes (reviewed in References (42–44)). As melanosomes accumulate at the termini of the melanocyte dendrites in the skin, they are pinched off and engulfed by surrounding keratinocytes. Disruptions in melanosomal transport (e.g. due to disrupted function of RAB27A, MYO5A or MLPH) and/or transfer result in Griscelli Syndrome (GS) (reviewed in References (44,45)).

Melanosomes are unique organelles in that they contain the pigment-specific catalytic and structural proteins involved in melanin production, such as tyrosinase. However, melanosomes belong to the LRO family, which also includes lysosomes, platelet dense bodies, etc. This relationship is highlighted by the fact that several other types of pigmentary disorders, including Chédiak–Higashi syndrome (CHS) and Hermansky–Pudlak syndrome (HPS), involve not only the disruption of melanosome structure and function, but also the disruption of lysosomes, platelets and other LROs (reviewed in References (38,46–49)). More than 15 different genes in mice have mutant phenotypes similar to these human lysosomal/pigmentary disorders, and to date nine of those have been definitively associated with various types of human HPS. Studies of these mouse and human phenotypes have shown that factors involved in the sorting/targeting of “lysosomal” proteins are also involved in melanosome biogenesis, and in fact this system has provided an ideal model to study organelle biogenesis. Many of the following proteins function in complexes important to the trafficking of proteins to LROs. Those complexes are known as BLOC-1, BLOC-2 and BLOC-3, although how their function is not yet clear (reviewed in References (48–52)).

### 145.2.4 Regulation of Melanosome Structure and Function

Although the chemical reactions involved in the production of different types of melanins from the amino acid tyrosine have been known for some time, it is only recently that the underlying complexity of the controls involved in producing melanins has been unraveled. There are many unusual properties of the melanin biopolymer that make it resistant to most approaches of chemical and physical analysis; in addition, the extremely reactive nature of melanogenic intermediates and their ability to rapidly and spontaneously form melanin *in vitro* has made the chemical pathway difficult to characterize. Tyrosinase is the only enzyme absolutely essential for melanin formation.

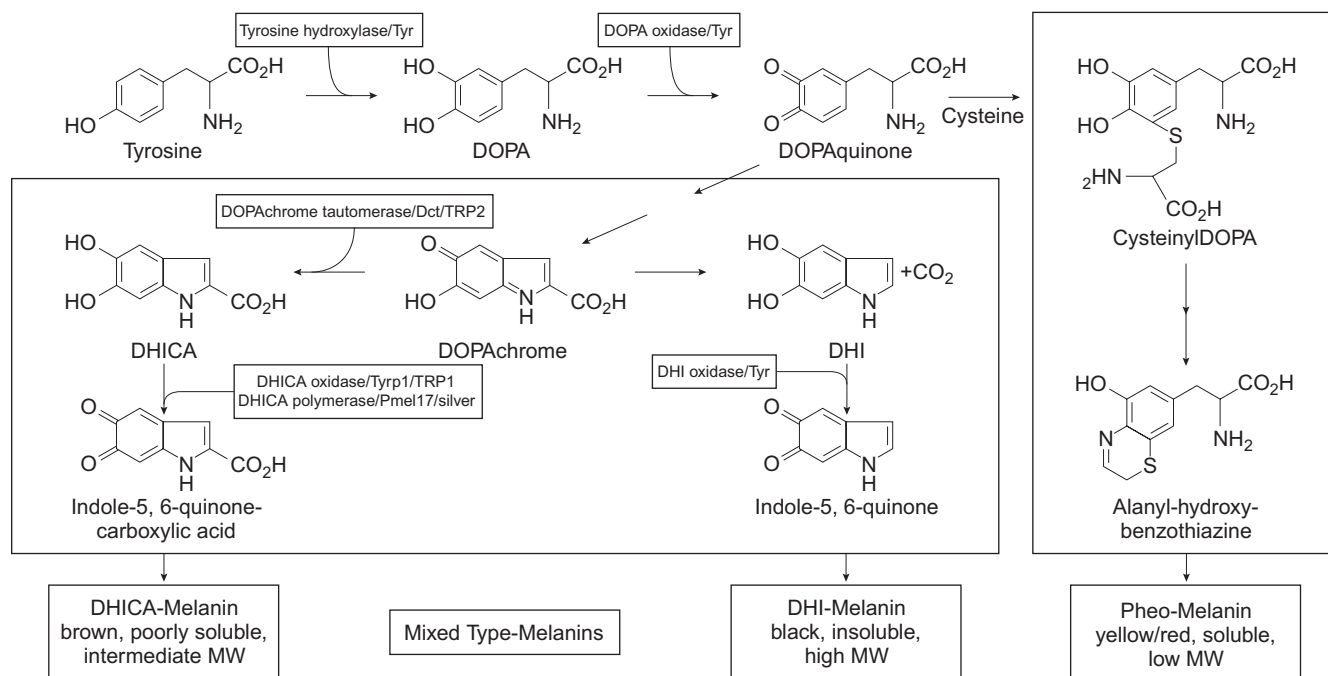

The early view of the regulation of melanin synthesis was that it depended directly on the amount of tyrosinase produced in melanocytes, because the substrate tyrosine was ubiquitous. However, it is now clear that the activity of tyrosinase and the production of melanin are regulated at several levels within melanocytes, and that the type of melanin produced is also actively regulated at several steps distal to the action of tyrosinase.

*In vitro*, the basic biochemical pathway for melanin formation from tyrosine depends directly on the function of tyrosinase. Tyrosinase (encoded by the *TYR* locus) has three distinct catalytic functions in melanin biosynthesis (53,54) (Figure 145-1). It is essential to melanin formation by virtue of its ability to catalyze the hydroxylation of tyrosine, the first and rate-limiting step in the melanin biosynthetic pathway, though tyrosinase can also utilize DOPA, DHI, or DHICA as substrates. This initial hydroxylase reaction is especially critical because there is negligible spontaneous hydroxylation of tyrosine in the absence of tyrosinase, particularly at the acidic pH within melanosomes. DOPAquinone, once formed, will continue through the melanogenic pathway by quickly cyclizing to form the indole ring structures known as leukoDOPAchrome and DOPAchrome. In turn, DOPAchrome will spontaneously decarboxylate *in vitro* to produce 5,6-dihydroxyindole (DHI), which will then rapidly oxidize to indole-5,6-quinone. Melanin was originally thought to consist simply of a homogeneous polymer of indole-5,6-quinone and related derivatives, but it is now clear that melanins are much more heterogeneous than that, containing mixtures of at least several additional intermediates in the pathway, some of them carboxylated (55–58).

Tyrosinase is synthesized as a *de novo* protein of approximately 60 kDa and is glycosylated en route to melanosomes to a final size of approximately 75 kDa. The catalytic functions of tyrosinase are highly dependent on its binding of two copper atoms per molecule at highly conserved metal ligand-binding motifs (59,60). The processing of tyrosinase (and the other melanogenic proteins) is tightly regulated in the Golgi apparatus and endoplasmic reticulum (ER) by the chaperone system for glycosylation and metal ligand binding (61–63). Many tyrosinase amino acid substitutions result in the retention of virtually all corresponding tyrosinase polypeptides in the ER (63–65), resulting in their premature proteolysis by proteasomes. The processing and trafficking of tyrosinase through subcellular compartments to melanosomes also requires correct intracellular pH (66,67); reviewed in (23,68,69).

*In vivo*, other biological constraints are put on the melanin biosynthetic pathway by factors that function downstream of tyrosinase and significantly alter the flow of the pathway. These factors include other enzymes (such as DCT/DOPACHrome tautomerase and TYRP1/5,6-dihydroxyindole-2-carboxylic acid [DHICA] oxidase), the availability of reactive sulfhydryl groups (e.g. cysteine), melanogenic inhibitors, and perhaps even other regulatory elements, such as intracellular pH and sorting proteins responsible for the trafficking of melanosomal proteins.

Two basic types of melanin can be produced in mammalian melanocytes: eumelanin, which is black or brown in color, and pheomelanin, which is red or yellow in color (reviewed in References (70–72)). The commitment

**FIGURE 145-1** Melanin biosynthetic pathway. The melanin pathway presents a summary of the known reactions and regulatory enzymes in eumelanogenesis and pheomelanogenesis.

to produce either type of melanin is made as soon as DOPAquinone is produced. If sulfhydryl groups, especially cysteine (73,74), are available in melanosomes, they will stoichiometrically capture DOPAquinone as it is produced, resulting in the production of cysteinylDOPAs. The nascent cysteinylDOPAs then undergo a series of poorly understood reactions that result in the cyclization of a second ring and the polymerization of those intermediates into a polymer called pheomelanin. Pheomelanins have many properties distinct from eumelanins in addition to their visible differences; they are significantly more soluble and of lower molecular weight, and presumably their functional properties are also quite distinct.

However, if sulfhydryl groups are absent/depleted in melanosomes, the eumelanogenic pathway will be followed. The DOPAquinone will be quickly converted to DOPACHrome, which represents yet another key regulatory point in the pathway (reviewed in References (75–77)). In the absence of other factors, DOPACHrome will spontaneously decarboxylate to form DHI, but in the presence of divalent metal cations and/or a melanogenic enzyme called DOPACHrome tautomerase (encoded by the *DCT* locus), the carboxylated intermediate DHICA will be produced. DHI and DHICA are not thought to be interconvertible chemically, so once this step is reached, the carboxyl content of the resulting melanin will be determined. If DHI is produced, it will be rapidly oxidized to indole-5,6-quinone and then quickly polymerized to large-molecular-weight biopolymers. However, if DHICA is produced, since it is relatively stable *in vivo* at the acidic environment of the melanosome, it will only slowly oxidize within melanosomes unless another enzyme is present to push the reaction further. In mice, an enzyme known as DHICA oxidase (encoded by the *Tyrp1* locus) has such an oxidase activity towards DHICA (78,79), and in the presence of Tyrp1, DHICA will be oxidized to the carboxylated indole-quinone and then to a melanin biopolymer. Although murine tyrosinase can oxidize DHI, it cannot utilize DHICA as a substrate. In humans, however, TYRP1 (encoded by the *TYRP1* locus) is not able to oxidize DHICA, whereas human tyrosinase is able to do this (80). TYRP1 has a more critical function in regulating melanogenesis via its stabilization of tyrosinase trafficking, as detailed below. DHICA-melanins appear to be of lower molecular weight, more soluble and of a brownish color when compared with DHI-melanins, which are very highly polymerized, insoluble and black (81). Melanins produced in mammalian melanocytes contain both carboxylated and decarboxylated intermediates, with the former typically constituting 50% or more of the total (82). In humans, melanins usually consist of mixtures of eumelanins and pheomelanins, termed mixed melanins. The exact ratio of the eumelanins and pheomelanins in mixed melanins probably varies with the individual. As noted above, it is not yet completely known what environmental factors influence which type

of melanin is made, or even whether human melanocytes can produce both types of melanins at the same time, or are similar to lower mammals, which produce only one or the other at any given time (for review, see Reference (27)). Characterizing the importance of incorporating these various intermediates (i.e. with or without sulfhydryl and/or carboxyl groups) to the structure and function of the melanins produced should provide important insights into understanding the regulatory controls over this pathway and their functional significance.

In addition to enzymatic components, several other melanocyte-specific proteins are critical for the unique structural arrangement of melanosomes, while others are involved in regulating the melanosomal environment that in turn regulates melanin production. The most important structural component is Pmel17 (also known as gp100), encoded by the *PMEL* locus. The processing of Pmel17 protein is critical to producing the myeloid-like fibers that transform melanosome structure from homogeneous to fibrillar, and on which melanins are deposited. MART1 is also crucial to the processing and trafficking of Pmel17, and disruption of MART1 function affects pigmentation. Other pump-like proteins thought to be present in melanosomes (or in key trafficking vesicles) include P/OCA2, SLC24A5, and SLC45A2, all of which are critical to the regulation of pigmentation. Expression and functions of these proteins are involved in regulating normal variation in the constitutive pigmentation of the hair, skin and eyes. These functions are also important in responding to environmental factors, and abnormal increases in their functions can cause various hyperpigmentary diseases, such as melasma and post-inflammatory hyperpigmentation (reviewed in References (23,24,83,84)).

### 145.2.5 Regulation of Melanin Production

The regulation of melanocyte differentiation *in vivo* is primarily under the control of the melanocortin 1 receptor (MC1R), its agonist  $\alpha$ -melanocyte stimulating hormone (MSH), and its antagonist agouti signal protein (ASIP). A large number of other receptor–ligand interactions also control melanocyte functions (differentiation, survival, migration, etc.), many of which are discussed above (e.g. EDNRB and EDN3, KIT and KITL); for reviews see References (23,24,84). The interactions of MC1R, MSH, and ASIP determine whether black/brown eumelanin versus red/yellow pheomelanin is synthesized, and how much of these melanins will be produced by melanocytes (85–90). The unstimulated state of melanocytes (i.e. in the absence of MSH) results in minimal production of melanin and predominant production of pheomelanin; the addition of MSH leads to a dramatic stimulation of eumelanin production in melanocytes, due to the increased expression of most melanosomal proteins (91). ASIP serves as an antagonist of MSH that prevents the activation of MC1R even in the presence of MSH, which in turn causes a decrease in pigment

production and a switch from eumelanin to pheomelanin synthesis. The human genes encoding MC1R, MSH, and ASIP are partially responsible for normal variation in the color and/or intensity of skin, hair, and eye pigmentation in humans, including the regulation of eumelanin/pheomelanin production (43,69).

Many additional loci also participate in the regulation of constitutive color, including a number of receptors expressed by melanocytes and the corresponding ligands produced by neighboring cells (keratinocytes, fibroblasts, etc.) (92–94) and by the environment (e.g. UV radiation) (25,26,95). The complex interactions involved in these processes are reviewed in References (10,11,23,24). The sum of those factors produces the full range of colors seen in tissues under normal conditions and responses, and over-activation of many of them have been associated with various hyperpigmentary diseases, e.g. melasma (96–100) and post-inflammatory hyperpigmentation (96). Most of those conditions are not inherited pigmentary disorders and thus are not within the scope of this chapter. Interested readers are referred to the reviews cited above for more detailed information.

### 145.2.6 Interactions and Regulation

It has been known for many years that there is a direct response of the pigment system in melanocytes to specific factors such as MSH and UV irradiation. Although the overall upstream sequences of the tyrosinase gene family genes (*TYR*, *TYRP1*, and *DCT*) are very different (101), each contains both shared transcriptional regulatory elements as well as functional promoter elements unique to each gene (102–104). Distally regulatory regions have been identified as far downstream as 15 kb. The most important regulatory element shared by the upstream regions of all three members of the tyrosinase gene family is the M-box (4), which is bound by the M-box binding factor MITF (105–108). *TYR* and *TYRP1* are thought to be coordinately regulated by melanotropic agents via cAMP-dependent protein kinase and protein kinase C (109). There are several lines of evidence indicating that cAMP is a key regulatory component, along with MITF, in the regulation of melanin biosynthesis (105,110). Nitric oxide (NO) is also thought to play a role in the induction of *TYR* gene expression via the cGMP pathway (111).

If expression of these genes is coordinately regulated, such regulation is more complex than simple activation of the three genes. In the mouse, tyrosinase enzymatic activity does not always correlate with *Tyr* mRNA levels or the amount of melanin produced (112), whereas levels of *TYRP1* protein do seem to directly correlate with the amount of eumelanin (113). In many (though not all) mouse melanocyte lines, *Dct* mRNA levels correlate with *DCT* activity (114). *Dct* is expressed very early in developing mouse embryos, usually around 10 days post-conception, whereas *Tyrp1* is expressed at

11.5 days post-conception, and *Tyr* transcripts at 13.5 days post-conception (115).

## 145.3 GENETICS AND DISORDERS OF HUMAN PIGMENTATION

### 145.3.1 Disorders of Melanocyte Development, Differentiation, or Migration—Piebaldism and Waardenburg Syndrome

Disorders of melanocyte development, differentiation, or migration typically result in abnormal pigmentary patterning, with congenital patches of hypopigmented skin and overlying hair that largely lack melanocytes, such as in piebaldism or in the various forms of Waardenburg syndrome (WS). Pigmentation in uninvolved areas is normal. Because of the visually evident phenotype, piebaldism was one of the first genetic disorders to be recognized, and is said (116) to be the first disorder for which a pedigree was presented.

A total of seven genes have thus far been associated with disorders of melanocyte development, differentiation, or migration, including *KIT* (piebaldism; OMIM 172800); *PAX3* (Waardenburg syndrome type I; WS1; OMIM 193500 and Waardenburg syndrome type III; WS3; OMIM 148820); *MITF* (Waardenburg syndrome type 2A; WS2A, OMIM 193510), *SNAI2* (WS2D, OMIM 608890), *EDNRB* (Waardenburg syndrome type 4A; WS4A; OMIM 277580), *EDN3* (Waardenburg syndrome type 4B; WS4B; OMIM 613265), and *SOX10* (Waardenburg syndrome types 2C; WS2C; OMIM 606662 and Waardenburg syndrome type 2E; WS2E; OMIM 611584).

**145.3.1.1 Piebaldism.** Piebaldism (OMIM 172800) presents with a characteristic pattern of white forelock and multiple symmetrical, irregularly shaped, white or depigmented macules. This condition has been reported in the literature under a variety of names, including partial albinism, familial white spotting, white forelock and piebaldism (117,118). The white forelock is usually present at birth or early in life, and may be only a few strands or a large patch of white hair. The underlying skin is white. The white macules occur on the face, trunk (typically ventral), and extremities, and the hair growing from them is white. The white forelock may be the only manifestation, and both hair and underlying skin may be involved. Areas of hyperpigmentation are often present within and along the borders of a hypopigmented macule. Melanocytes are typically absent in the white patches of skin and hair follicles of the white hair. Piebaldism is autosomal dominant in inheritance (118). A child born to affected parents was presumed to be homozygous for piebaldism; the child had complete absence of cutaneous pigment and blue eyes (119).

Piebaldism results from mutations or deletions of *KIT* (117,120–129). This was first suspected on the basis of

the identification of *Kit* deletions in mice with dominant white spotting (W) (130–133), the localization of human *KIT* at chromosome 4q11–q13 (134,135), and the identification of a patient with piebaldism associated with an interstitial deletion at chromosome 4q12 (136). The W locus of the mouse was shown to represent the *Kit* proto-oncogene, which encodes a transmembrane receptor tyrosine kinase (130) that is expressed in mast cells, melanoblasts/melanocytes, hematopoietic stem cells, intraepithelial lymphocytes, interstitial cells of Cajal, and germ cells. With respect to the pigment-related phenotype, *KIT* loss of function mutations may affect the development and/or migration of melanocytes, producing the phenotype of piebaldism.

The human *KIT* gene has 21 exons spanning 34 kb (135,137,138), with evidence of alternative mRNA splicing (138). In a human family with piebaldism, a *KIT* missense mutation was identified, which exhibited linkage with piebaldism in this family with a lod score of 6.02 at  $\theta = 0$  (120). Another case was shown to have deletion of both *KIT* and the adjacent *PDGFRA* genes (139). As in the mouse, different alleles of the human *KIT* gene result in a spectrum of phenotypes ranging from mild to severe forms of piebaldism (140). A missense mutation, R796G, located in a highly conserved region of the tyrosine kinase domain, has been associated with piebaldism and deafness (128). Other mutations in the *KIT* gene can result in mastocytosis or in gastrointestinal stromal tumors (141).

The ligand for the *KIT* receptor is *KIT* ligand (*KITL*) (142–144), encoded by the *KITLG* gene located at 12q22 (145). In the mouse, *Kitlg* gene mutations at the steel (*Sl*) locus prevent its binding to the receptor, resulting in a spotted phenotype identical to that of mutations in the W locus (142,144,145). The *Kitlg* mutant phenotype also affects erythropoiesis and germ cell development, as observed with the W locus. While mutations in human *KITLG* might be expected to result in a phenotype similar to that of piebaldism (145), no patients with a piebaldism-like phenotype have been identified with mutations in *KITLG* (140), though a missense substitution in this gene has been associated with familial progressive hyperpigmentation (146).

Another potential human piebaldism gene is *ADAMTS20*, which encodes a metalloprotease that is secreted and is involved in degradation of the extracellular matrix and in tissue remodeling (reviewed in References (16,147)), and which is essential for melanoblast migration and survival (148). In the mouse, *Adamts20* mutations cause belted (*bt*) white-spotting (149).

**145.3.1.2 Waardenburg Syndrome (WS).** The classic phenotype of Waardenburg syndrome consists of the combination of lateral displacement of the inner ocular canthi with a broad nasal ridge (hypertelorism), white forelock (poliosis), different colors of the two irides (heterochromia irides), white eyelashes, white areas of skin (leukoderma), hyperplasia of the medial portion of the eyebrows, and

congenital sensorineural (cochlear) hearing loss (150–152). In fact, four main types of WS are distinguished: WS type 1 (WS1) with lateral displacement of the ocular inner canthi (dystopia canthorum) (OMIM 193500); WS type 2 (WS2) without dystopia canthorum (OMIM 193510); WS type 3 (WS3) with limb muscle hypoplasia and joint contractures (Kline–Waardenburg syndrome; OMIM 148820); and WS type 4 with Hirschsprung disease (Waardenburg–Shah syndrome; OMIM 277580) (150,151,153). WS1, WS2, and WS3 are autosomal dominant, whereas WS4 is autosomal recessive in inheritance, as reviewed in References (150,151,153). However, the genetics of WS are complex, involving a number of different genes, with mutant phenotypes and patterns of inheritance that do not correspond perfectly to the four clinical WS types. Thus, WS1 and WS3 result from mutations of *PAX3* (154); WS2 results from mutations of *MITF* (155,156) and *SNAI2* (157); and WS4 can result from mutations of *EDN3*, *EDNRB*, or *SOX10* (150).

**145.3.1.2.1 WS1 and WS3.** WS1 is an autosomal dominant disorder characterized by congenital piebald-like hypopigmentary patches of skin and overlying hair, heterochromia irides, congenital sensorineural hearing loss and dystopia canthorum. WS3, also known as Kline–Waardenburg syndrome (158), is similar, but also includes upper limb anomalies (147).

Initial identification of the gene associated with WS1 was based on similarity to the mouse splotch (*Sp*) phenotype, which involves spotty areas of hypopigmentation. The region of mouse chromosome 1 containing the *Sp* locus is syntenic to the region of human chromosome 2 to which WS1 had been mapped (2q35–2q37) (159–161). *Pax3* mutations were identified in *Sp* mice (162), and human *PAX3* (previously called *HuP2*) was then shown to contain mutations in patients with WS1 (163,164). In fact, mutations in *PAX3* result in both WS1 and WS3, as well as in Craniofacial–deafness–hand syndrome (CDHS) (147).

*PAX3* consists of 10 exons spanning approximately 100 kb (165) at chromosome 2q35. A large number of *PAX3* mutations have been identified in patients with WS1 or WS3, typically with specific private mutations being found in a specific family (147,152,161,166–169). Many *PAX3* mutations appear to result in complete loss of function, the dominant nature of WS1 and WS3 suggesting haploinsufficiency for dosage of functional *PAX3* protein (164). Mutations that produce an activity level of greater than 50% of normal result in only dystopia canthorum. Null mutations that reduce the level of active protein to 50% in the heterozygote also affect melanocyte migration, resulting in patches of depigmentation. A few mutations produce a level less than 50% and are thought to act as a dominant negative. These individuals have limb muscle defects and neural tube defects and are representative of WS3.

*PAX3* encodes a member of the paired box domain family of transcription factors that are homologous to

the *Drosophila* *prd* homeobox gene, in which mutations result in the gooseberry phenotype that affects segmentation and segment polarity (159,161,163). The highly conserved PAX3 protein contains three distinct functional domains: a paired box, a conserved octapeptide domain, and a homeobox domain. The mouse *Pax3* gene (previously known as *splotch*; *Sp*) plays a role in pattern formation in the embryonic neural crest, and the high degree of homology between mouse Pax3 and human PAX3 proteins suggests that the human PAX3 plays a similar role in the neural crest development (170,171). PAX3 regulates the differentiation of melanocytes by modulating transcription of *MITF*, which in turn regulates downstream transcription of many melanocyte-specific genes (17,168,172).

**145.3.1.2.2 WS2.** The phenotype of WS2 is similar to that of WS1, but lacks dystopia canthorum. There are several genetic subtypes of WS2. WS2A (OMIM 193510) results from mutations in *MITF* (152,156,173–176). WS2B (chromosome 1p21–13.3; OMIM 600193) and WS2C (chromosome 8p23; OMIM 606662) have been mapped in individual families, but the corresponding genes have not yet been identified. WS2D (OMIM 608890) results from mutations in *SNAI2* (also known as *SLUG*) (157). WS2E (OMIM 611584) results from mutations in *SOX10*, which is also associated with WS4 (OMIM 277580).

Mutations of *MITF* cause WS2A, as well Tietz syndrome (OMIM 103500), and contribute to digenic inheritance in a form of ocular albinism with sensorineural deafness WS2-OA; (OMIM 103470); (177). The microphthalmia (*Mitf*) gene was first identified in mice, and encodes a protein containing a basic helix-loop-helix-zipper (bHLH-ZIP) motif, which is associated with a family of transcription factors (178). The human *MITF* gene is located at chromosome 3p12.3–p14.1 (156), and consists of nine exons, including four different alternative first exons, each having unique promoter sequences (179). Depending on which promoter is used to initiate transcription, a different protein isoform, MITF-A, -H, -B or -M, is produced. Promoter M is melanocyte-specific, promoter A directs expression in the RPE, cervical cancer and melanoma cells, while promoter H directs expression in the RPE and cervical cancer cells. The MITF protein is a transcription factor that regulates processes involved in melanocyte development, differentiation, function and survival (180). MITF binds to the M-box and E-box, two melanocyte-specific promoter motifs found in the 5' region of genes encoding tyrosinase-related proteins and many other pigmentation-related genes (reviewed in (30,147,181)). Many different human *MITF* mutations have now been identified, and appear to produce WS2 by means of haploinsufficiency for MITF function (147). Some mouse *Mitf* alleles, when homozygous, result in a completely unpigmented, deaf mouse with defective eye development, whereas other *Mitf* alleles have a less severe effect in homozygotes.

Rare patients have been identified with WS2D, resulting from deletions of 8q11 that include the *SNAI2* gene (also known as *SLUG*). *SNAI2* consists of three exons that encode a 268-amino acid protein with a molecular mass of approximately 80 kDa. In two of 38 unrelated patients with WS2 and no mutation in the *MITF* gene, homozygous deletions of the *SNAI2* gene were identified (157). Similarly, *SNAI2* deletions were also observed in patients with piebaldism who lacked *KIT* mutations (182), but who presumably should be reclassified as having WS2D. *SNAI2* is a transcription factor containing five zinc finger regions (183). *SNAI2* is important in the initial stages of cell migration from the neural tube (184), and is thought to function by inducing the epithelial–mesenchymal transition that is involved in development, more specifically migration and/or survival, and other cellular processes (reviewed in (147)).

WS2E is similar to WS2A, but may additionally include neurological abnormalities such as mental impairment, myelination defects, and ataxia. WS2E results from mutations of *SOX10* (185–188). *SOX10* is also associated with WS4 and PCWH syndrome (see below) (147).

**145.3.1.2.3 WS4.** WS4 (OMIM 277580) is similar to WS1 but additionally includes Hirschsprung disease. WS4 is divided into three genetic subtypes (185,189–192), resulting from mutations in *EDNRB* (WS4A; OMIM 277580), *EDN3* (WS4B; OMIM 613265), or *SOX10* (WS4C; OMIM 613266).

Mutations in *EDNRB*, encoding the receptor for ligand endothelin-3, result in WS4A, ABCD syndrome (previously known as albinism and black locks syndrome), and genetic susceptibility to Hirschsprung disease (HSCR2; aganglionic megacolon) (193). *EDNRB* is located at chromosome 13q22 (194). Targeted mutations of mouse *Ednrb* result in a phenotype similar to human WS4A, including coat color spotting (195).

Mutations in *EDN3*, encoding endothelin-3, result in WS4B, as well as in a genetic susceptibility to Hirschsprung disease (HSCR4) and idiopathic congenital central hypoventilation syndrome (CCHS; OMIM 209880). *EDN3* is located at chromosome 20q13.2. In the mouse, targeted *Edn3* mutations result in a phenotype similar to that resulting from disruption of *Ednrb*, providing an early suggestion for a second locus associated with WS4 in humans (196), and indicating that the EDN3-EDNRB ligand–receptor interaction is important for the development of epidermal melanocytes and enteric neurons.

Mutations in *SOX10* cause WS4C, as well as WS2E, and PCWH syndrome (147,197,198). *SOX10* is located at chromosome 22q13.1 (191). *SOX10* belongs to the SOX family of transcription factors, and is involved in regulating the early development of the neural crest and the migration of melanoblasts (199,200). *SOX10* also participates in regulating transcription of *MITF*, and also directly regulates transcription of *DCT* and *EDNRB* (201,202).

**145.3.1.3 Albinism–Deafness Syndrome (ADFN).** A large Moroccan Sephardic Israeli family has been described that includes multiple males with piebald-like white spotting of skin and overlying hair and profound congenital deafness inherited in an X-linked recessive pattern (OMIM 300700), with evidence of hearing defect in carrier females (203,204). The *ADFN* gene has been mapped to chromosome Xq24–q26 (205), but has not yet been identified. It remains uncertain whether other reports of similar clinical findings in other patients in fact represent the same entity (206,207).

### 145.3.2 Disorders of Melanocyte Function—Albinism

Albinism is a heterogeneous group of genetic disorders, almost all autosomal recessive, which are characterized by congenital global reduction of pigmentation of the skin, hair, and eyes, either alone or with other systemic abnormalities (for reviews, see References (208,209)) (Table 145-1). Because of the visually evident phenotype, albinism was the first genetic disorder ever recognized, with clear descriptions in many ancient texts (Figure 145-2). The most severe form, oculocutaneous albinism (OCA) is estimated to occur with a prevalence of approximately 1 in 18,000 to 20,000 in the US population, though accurate population-based surveys have never been done. The ranges of clinical phenotypes of the different forms of albinism overlap substantially, and, with the exception of CHS, the different forms of OCA cannot be distinguished on clinical grounds and require molecular analysis.

Patients with albinism can have little or no integumentary pigment ranging all the way to near-normal, and in general the degree of clinical severity is directly related to the amount of melanin pigment. Thus, lack of melanin pigment in the skin can make patients subject to severe sunburn and, over time, skin damage and susceptibility to skin cancer, particularly in parts of the world with high rates of UV exposure. It is therefore essential that patients with all forms of albinism avoid unnecessary sun exposure and make liberal use of sunscreen and other forms of sun protection.

In addition to deficient integumentary pigmentation, all forms of albinism also include reduced melanin pigmentation of the iris (Figure 145-3) and retina (Figure 145-4). Melanin plays key (albeit unknown) roles in development of the optic tracts, and patients with albinism thus manifest a stereotypic set of optic abnormalities that occur independently of the specific gene involved, and instead appear to relate in severity to the degree of melanin deficiency during optic tract development during fetal development and postnatal life (210–219). These defects are not observed in obligate heterozygotes for these recessive diseases. Deficient iris pigmentation results in photophobia, and deficient retinal pigmentation results in foveal hypoplasia and

**FIGURE 145-2** Adult European-derived female with OCA1A.

consequent reduced visual acuity that cannot be corrected to normal (“low vision”) (76,219–221), with eventual Snellen visual acuity ranging from 20/80 to 20/400. In general, clinical severity correlates with the amount of melanin pigment in the eye (222). Foveal hypoplasia does not interfere with color vision (223–225). Aberrant neural projections from the retina to the brain, with neuronal misrouting at the optic chiasm, lateral geniculate nucleus and motor nuclei (223,226–229) (for review, see References (230,231)) (Figure 145-5), result in stereoscopic depth perception, horizontal pendular nystagmus, and often strabismus (221,222,232). The response to flash or pattern-onset stimuli in a visual evoked response test is often used to establish a diagnosis of albinism in children (including neonates) (233), the magnitude of the visual evoked potential (VEP) changes generally correlate with the clinical features of albinism (234). Frequently, photophobia and low vision are among the most important impediments to normal daily life in persons with albinism. While most children with albinism function well in regular school, attention should be paid to special needs for vision, including large-print reading materials and preferential seating in the classroom.

Pigmented melanocytes occur in the inner ear; in the stria vascularis, which provides the driving current for the hair cells, the sensory receptors in the inner ear. While the absence of melanin pigment in the inner ear makes animals with albinism more susceptible to noise-induced hearing loss (235,236), in humans albinism is not associated with auditory abnormalities.

In addition, the visually evident lack of skin and hair pigmentation can result in significant psychosocial morbidity due to real or perceived social stigmatization and isolation, particularly in individuals derived from ethnic groups in which dark skin and hair pigmentation is the

**FIGURE 145-3** Iris transillumination. A) Normally pigmented iris with no transillumination on slit-lamp examination; B) Grade 4 (full) iris transillumination in an individual with OCA1A.

**FIGURE 145-4** Fundus abnormalities in OCA. A) Normal retinal pigment from a normal individual; B) Absence of retinal pigment, with visualization of the choroidal vessels, from an individual with OCA1A.

**FIGURE 145-5** Distribution of retinal ganglion fibers in an eye with normal pigment (left) and an eye in albinism (right). With normal ocular pigment, the nasotemporal border corresponds to the fovea, with the temporal fibers projecting to the ipsilateral lateral geniculate nucleus. With albinism, the nasotemporal border is shifted 20° or more into the temporal retina, resulting in most retinal ganglion fibers crossing at the chiasm and projecting to the contralateral lateral geniculate nucleus. (From Creel, D. J.; Summers, C. G.; King, R. A. *Visual Anomalies Associated with Albinism*. Ophthalmic Paediatr Genet. 1990, 11 (3), 193–200, with permission.)

norm. An extreme and particularly horrific manifestation of this in recent years has been the systematic murder and harvesting of body parts from people with albinism for their imagined magical properties in Kenya, Tanzania, Burundi, and other parts of east Africa, where ironically, the prevalence of albinism is perhaps the highest in the world. Useful information for individuals with albinism is available from the National Organization of Albinism and Hypopigmentation (NOAH) (<http://www.albinism.org>).

The classification of the different types of albinism has evolved considerably over the past several decades.

Previously, classification was based on clinical grounds and on biochemical testing using the hair bulb incubation test, distinguishing OCA as “tyrosinase-negative” and “tyrosinase-positive” types (237–240). Both of these approaches are now known to be unreliable. Diagnostic classification is now based on molecular analysis, with a total of 18 genes thus far identified as being responsible for different types of albinism in humans, involving deficient melanin biosynthesis, defective melanosome biogenesis, or defective melanosome transport. Four genes are associated with oculocutaneous albinism

(OCA), in which the recessive phenotypes are largely due to reduced biosynthesis of melanin pigment, while the number, distribution, and structure of the melanosomes and melanocytes in the skin, hair follicles, and eyes remains normal: *TYR* (oculocutaneous albinism type 1; OCA1; OMIM 203100), *OCA2* (oculocutaneous albinism type 2; OCA2; OMIM 203200), *TYRP1* (oculocutaneous albinism type 3; OCA3; OMIM 203290), and *SLC45A2* (oculocutaneous albinism type 4; OCA4; OMIM 606574) (see Table 145-1). Mutations in these same genes can also result in clinically milder phenotypes known as “autosomal recessive ocular albinism” (AROA), in which the optic defects are similar to in OCA, though less severe, while there may be relatively apparent integumentary hypopigmentation. One additional gene, *GPR143*, is associated with an X-linked recessive form of ocular albinism (OA1; OMIM 300500). In addition, a total of 13 different genes are associated with three different syndromic disorders in which oculocutaneous albinism occurs in concert with life-threatening systemic manifestations: Hermansky–Pudlak syndrome (HPS; OMIM 203300), Chédiak–Higashi syndrome (CHS; OMIM 214500), and Griscelli syndrome (GS). To date, mutations in nine genes have been associated with HPS, one with CHS, and three with GS. Some individuals with albinism who do not have detectable mutations in any of these genes may represent other types of albinism or other pigmentation disorders associated with mutations in genes that have yet to be identified.

#### 145.3.2.1 Oculocutaneous Albinism (OCA).

**145.3.2.1.1 OCA1.** Oculocutaneous albinism type 1 (OCA1; OMIM 203100, 606952) is the classic form of albinism, and because of its visually evident phenotype was the first genetic disorder to be recognized and studied (241–243). The clinical phenotype includes absent or greatly reduced pigmentation of the skin (Figure 145-2), hair, and eyes (Figures 145-3 and 145-4), predisposing to sunburn, long-term skin damage from ultraviolet radiation, and skin cancers, as well as reduced visual acuity, nystagmus, strabismus, and photophobia, as described above.

OCA1 results from mutations of the *TYR* gene (OMIM 606933), encoding tyrosinase, which catalyzes the rate-limiting initial steps of melanin biosynthesis (described above). Human OCA1 is thus homologous to the classic *c*-albino phenotype of the mouse (5). The human *TYR* gene is located at chromosome 11q14.3 (244), and encodes a 529 amino acid polypeptide with molecular weight 62.6 kDa. The *TYR* gene consists of five exons spanning approximately 120 kb (245,246). More than half of the coding region is within exon 1 (819 bp), with exons 2 to 5 ranging from 148 to 225 bp. A second locus containing tyrosinase-related sequences is a partially duplicated, non-transcribed pseudogene on chromosome 11p11.2–cen (*TYRL*) (245,247), consisting of the distal portion of IVS3 through sequences downstream of exon 5. *TYR* and *TYRL* have 98% nucleotide sequence identity within exons 4 and 5, complicating molecular diagnostics

of OCA1 using polymerase chain reaction (PCR) based approaches, and requiring the use of PCR primers that differentially amplify *TYR* and not *TYRL*. *TYRL* exists in the gorilla but not the chimpanzee, indicating that the *TYRL* duplication occurred relatively recently in primate evolution (248). Furthermore, the *TYR* gene is a member of a multi-gene family that also includes *TYRP1* and *DCT*, although these related genes do not interfere with specific PCR amplification of *TYR* in practice.

OCA1 has been estimated to occur with a prevalence of about 1 in 40,000 in the EUR population; however, no accurate population-based surveys have ever been done. Recent comprehensive sequence-based mutation surveys of the known OCA genes have demonstrated unambiguously that OCA1 is the most frequent type of OCA in the EUR population (249) and in Japanese (250), whereas OCA2 is the most common form of OCA in African-derived individuals. Many pathological *TYR* mutations have been identified, the great majority being point mutations—missense, nonsense, frameshift, and splice junction mutations (The Albinism Database, <http://albinismdb.med.umn.edu/>). Large gene deletions of human *TYR* have been observed (251), but are very rare. The majority of patients with OCA1 are compound heterozygotes with different mutant maternal and paternal alleles, with many families having “private” mutations, but a few common mutations do exist (249,252,253); in the EUR population these are missense alleles T373K and P81L. A complete list of *TYR* mutations and the ethnicity of individuals in which they were observed can be found on the Albinism Database (<http://albinismdb.med.umn.edu/>).

The major determinant of a patient’s OCA1 phenotype is the amount or type of residual tyrosinase catalytic activity, although in patients who do have residual activity, the constitutional pigment background of the affected individual also plays a role (254). Thus, the range of clinical variation spans so-called “OCA1A” (“tyrosine-negative”: Figure 145-2; (76,253,255–259), “OCA1B” (“yellow albinism”): (237,254,260–263), to “autosomal recessive ocular albinism” (see below). The majority of the mutations reported result in no residual tyrosinase activity. There is also a subset of mutations associated with about 5–10% residual activity that, in a homozygous or heterozygous dose, result in OCA1B with varying amounts of cutaneous and ocular pigmentation. Several of the *TYR* missense substitutions result in temperature-sensitive, thermolabile forms of tyrosinase (261,264) that are misfolded, retained in the endoplasmic reticulum, and are prematurely degraded by proteosomes (61,63–65,67,265,266); these are thus analogous to the Siamese cat and the Himalayan mouse, both of which are the result of a temperature-sensitive enzyme. An unusual mechanism by which *TYR* mutations might affect enzyme function is by interfering with binding its two copper (Cu) atoms, and it has been noted that *TYR* missense substitutions associated with OCA1 cluster

in the Cu-A and Cu-B binding regions of the protein (54,257,263), perhaps affecting  $\alpha$ -helical regions that ligand the copper atoms (267), rendering the enzyme inactive (60,267).

One important special case involving *TYR* (or occasionally other OCA loci) is so-called “autosomal recessive ocular albinism” (AROA), in which the ocular manifestations of OCA predominate (though they are less severe than in typical OCA), while the integumentary manifestations are minimal or absent (268). AROA was described before the availability of molecular analysis. These have subsequently shown that virtually all cases of AROA are associated with mutations in *TYR* (269,270). Specifically, almost all patients with clinical AROA are compound heterozygotes for an OCA1 mutant allele and a non-OCA1 allele containing a common missense polymorphism of *TYR* that is frequent in the EUR population, R402Q (245). The R402Q variant tyrosinase polypeptide is temperature-sensitive (264) and thus is retained in the endoplasmic reticulum and degraded (65). However, this variant retains approximately 25% residual catalytic activity even at 37 °C; thus, patients with AROA have about 13–25% of residual tyrosinase activity, depending on the other allele. It seems likely that residual activity might be less at the elevated temperature of the fetus, affecting the developing optic tracts, but that residual activity might be much higher at the relatively cool temperature of postnatal skin, resulting in a fixed neurological defect but near-normal integumentary pigmentation. While the prevalence of *TYR*-related AROA is not known, the prevalence of the OCA1/R402Q genotype is estimated at about 1 per 300 individuals in the EUR population.

The *TYR* promoter region specifies four transcriptional start sites, with the major 5' start site –79 bp 5' to the ATG translation initiation codon, and minor 5' start sites at –75, –46, and –42 bp (245,271). Analyses of transgenic mice with different lengths of the *Tyr* promoter have shown that as little as 270 bp of the proximal promoter sequence produces cell-specific and temporal-specific expression, but not wild-type levels of pigmentation (272,273), while production of transgenic mice using a 250-kb yeast artificial chromosome containing over 150 kb of the 5'-flanking sequence conferred wild-type levels of pigmentation (274). Within the proximal –270 to –80 nt region, several positive and negative transcriptional regulatory elements have been identified (246,271,275–277). In human *TYR*, these include TATA (–106 bp) and CAATT (–199 bp) motifs, as well as a ~230-bp (GA)<sub>n</sub> polymorphic microsatellite at about –713 nt, the functional significance of which is unknown (271,278,279), and which has not been associated with normal pigmentary variation. In mouse *TYR*, a critical 11-bp regulatory element, AGTCATGTGCT, is located –104 nt upstream of the transcriptional start site, termed the “M-box” (106,275,280). A second M-box, sometimes termed the “E-box,” is located at –12 nt (281,282).

M-box elements occur in the promoters of all three members of the *TYR* gene family both in mice and in humans and are essential for melanocyte-specific expression (101,103,106,283). Within the 11-bp M-box motif, a 6-bp motif, CANNTG, binds a family of helix–loop–helix transcription factors (178); in melanocytes, the most important of these is the microphthalmia-associated transcription factor (MITF), encoded by the *MITF* gene (see above). MITF binds both the M-box and the TDE, a cis-acting enhancer element located approximately 1.86 kb upstream of the transcriptional start site (107,246,282,284,285). The 39-bp TDE core element contains the 6-bp M-box core motif, and directs melanoma cell-specific expression of a reporter gene (107) and in fact is the strongest M-box in the *TYR* promoter (285). In the mouse, MITF directs specific transcription of the *Tyr* and *Tyrp1* genes in melanin-producing cells (286). Nevertheless, the M-box alone cannot confer cell-specific expression of pigment genes in melanocytes (287,288), as MITF is expressed in cells that express and do not express pigment-specific genes (101,106). The M-box can activate transcription of reporter genes in multiple cell types, and deletion of the M-box does not completely abolish *TYR* transcription. A second, ubiquitous transcription factor also binds the M-box, although its identity and role in melanocyte-specific transcription are unknown (106). Other transcription factors expressed in the melanocyte, including Brn2, TBX2, PAX3, SOX10, N-Oct-3 and N-Oct-5, also are involved in controlling transcription of pigment-specific genes (110,289) and bind other regulatory elements in the proximal *TYR* promoter.

A more distal transcriptional regulatory element is located –12 to –15 kb upstream of the transcriptional start site (290–292), in a 200-bp region containing two DNase I hypersensitive sites embedded within a scaffold/matrix attachment region (S/MAR) (290,293). This region is rearranged in the chinchilla-mottled (*cm*) *Tyr* mutant allele of mouse, resulting in hypopigmentation, indicating that this region plays an important role in *Tyr* expression (291). DNase I footprinting at this site revealed a binding site containing the palindrome TGACTTTGTCA, which resembles the binding motifs for both a cAMP-responsive element-binding (CREB) transcription factor and the activator protein-1 (AP1) binding factor (290). A similar sequence occurs in human *TYR* –9 kb upstream of the *TYR* transcriptional start site (294–296), which also exhibited DNase hypersensitivity in humans. The core sequences of this region were shown to specifically increase transcription of a reporter gene in melanocytes in conjunction with the *TYR* proximal promoter (294–296).

**145.3.2.1.2 OCA2.** Individuals with albinism having yellow hair and white skin, or brown hair and skin, have been documented in many historical records, particularly those related to the European exploration of the African continent (242,297–301). The first major insight into

the separation of OCA into different types was provided by the hair bulb incubation test which, while unreliable, seemed to distinguish individuals with “tyrosine-negative” versus “tyrosine-positive” OCA (237–239). The fact that this represented true genetic locus heterogeneity was demonstrated by finding normally pigmented offspring from a mating between one individual with tyrosinase-negative OCA and another with tyrosinase-positive OCA (238,302).

Individuals with oculocutaneous albinism type 2 (OCA2; OMIM 203200) exhibit a recessive phenotype very similar to that of OCA1 (Figure 145-6), though on the average slightly less severe in all respects, particularly in patients of African descent (242,297–301,303–306). Hair may be pigmented at birth or early in life, and many individuals with OCA2 develop localized (nevi, freckles, and lentigines) skin pigment, often in sun-exposed regions of the skin. Many affected individuals accumulate pigment in their hair and eyes during their lifetime, and this is more marked in individuals from darker ethnic groups. OCA2 is found in all populations, and it is the most prevalent type of OCA in equatorial Africa (300,304,307–313), with an estimate prevalence of 1 in 3900 in southern African blacks (313) and 1 in 1400 in Tanzania (311). Unfortunately, the prevalence of skin cancer is very high in patients from these regions, due to very high rates of UV exposure. Several smaller isolated populations have also been reported to have a high frequency of OCA2, the apparent result of founder effects (240,314,315). The estimated carrier frequency for this deletion in African Americans is 1 in 200 to 1 in 500 (316).

OCA2 results from mutations of the OCA2 gene (OMIM 611409) on chromosome 15q11.2–q13 (317,318), a region that had been shown to be linked to OCA2 (319). OCA2 is the human homolog of the pink-eyed dilute (*P*) locus of the mouse (317,318,320–325). The human OCA2 gene is quite large, consisting of 24 exons, with the translational initiation codon in exon 2, and encodes an 838 amino acid polypeptide with molecular mass of 92.8 kDa (318). OCA2 is a transmembrane protein containing 12 membrane-spanning regions (318,325), and it shares homology with several small molecule transport proteins of lower species. It has been suggested that OCA2/P might function as a transporter within melanosomes (318,326), but as yet there is no conclusive evidence of its function (327–331). Studies of OCA2/P localization and function indicate that the protein functions in the sorting of TYR and TYRP1, and in the mouse, *Oca2* mutations disrupt the trafficking of those enzymes to melanosomes, leading to the hypopigmented phenotype (332). It has also been suggested that, given the importance of organellar pH in the correct sorting of proteins (333,334), particularly those trafficking to melanosomes (66,67), that the function of the OCA2 protein may be to regulate the pH of sorting vesicles involved in intracellular trafficking and subcellular

FIGURE 145-6 Female, age 4 years, with OCA2.

localization of tyrosinase (68,250,318,335). There is no direct functional assay for the OCA2 protein, though distinction between pathogenic mutations and polymorphisms of OCA2 can be accomplished by transfection assay of *p*-deficient mouse melanocytes (336).

OCA2 is the most common type of OCA in individuals of African descent (316,337), and is the second most common type of OCA in EUR individuals (249). The most common OCA2 gene mutation is a 2.7-kb deletion that accounts for 60–90% of mutant alleles in individuals from southern and sub-Saharan African descent (311,316,323,337), and which also occurs in the Brandywine isolate of Maryland as a founder mutation (240). Mutations in OCA2 also are the cause of so-called “brown” oculocutaneous albinism (BOCA) (338). A large number of OCA2 mutations have been identified in patients from other populations, including many missense mutations, as well as frameshift, nonsense, and splice junction mutations (249,252,253,269,315,323,338–343). As for OCA1, a small number of patients with AROA have mutations in the OCA2 gene (270,323), suggesting that these patients likely have substantial residual function. Other OCA2 variants act as the major determinant in blue eye color (68,344–348) and as a major risk factor for malignant melanoma (349).

The discovery of the OCA2 gene also depended on its involvement in hypopigmentation observed in many patients with the Prader–Willi (PWS) and Angelman (AS) syndromes (317,318,350–354). PWS is a developmental syndrome that includes neonatal hypotonia, hyperphagia and obesity, hypogonadism, small hands and feet and mental retardation

associated with characteristic behavior (355–359). Approximately 70% of PWS patients have an interstitial deletion on the long arm of the paternally-derived chromosome 15, and most PWS patients without a deletion of the chromosome 15q(pat) have uniparental disomy for the maternal chromosome 15. Many PWS patients with 15q deletions have clinically apparent hypopigmentation (350,353,354,360,361); moreover, about 1% of PWS patients have concomitant OCA2 (318,322).

Similarly, AS is a complex developmental disorder that includes developmental delay and severe mental retardation, microcephaly, neonatal hypotonia, ataxic movements, and inappropriate laughter (362–364). Most cases are the result of interstitial deletion of chromosome 15q11–q13. Hypopigmentation occurs in more than 50% of AS patients (352), correlating with the presence of a deletion of 15q(mat) (365,366), and again about 1% of AS patients have concomitant OCA2. Together, these findings suggested that PWS and AS patients with concomitant OCA2 might be hemizygous for OCA2 mutant alleles on the intact chromosome, or possibly might have uniparental isodisomy for the mutant allele. This hypothesis has been confirmed by the demonstration of hemizygous OCA2 mutations in patients with PWS (318,322) and AS (367,368).

**145.3.2.1.3 OCA3.** Oculocutaneous albinism type 3 (OCA3; OMIM 203290) results from mutations in *TYRP1*, located at chromosome 9p23 (369–371), and which encodes a 537 amino acid TYRP1 polypeptide with molecular weight of approximately 60 kDa (372,373). Human OCA3 thus corresponds to the brown (*b*) phenotype of the mouse (374,375), which results from mutations of *Tyrp1* and is associated with a brown rather than a black coat (4). It seemed likely that a human OCA phenotype would be associated with mutations of human *TYRP1*, and an African-American child with generalized hypopigmentation was identified with a homozygous *TYRP1* frameshift mutation (376). The boy, one of dizygotic twins, had light brown skin and hair and blue-gray irides at birth, whereas his twin had darker skin and hair consistent with normal pigmentation for an African-American newborn. Melanocytes cultured from the affected twin contained no TYRP1 protein or *TYRP1* mRNA, and DHICA oxidase activity was greatly reduced. These cells produced reduced amounts of insoluble melanin and appeared brown rather than the black color found with normally pigmented African-American control melanocyte cultures.

Genetic linkage studies subsequently showed that OCA3 corresponds to “rufous” or “red OCA” (OMIM 278400) which mapped to the *TYRP1* locus on chromosome 9p in the South African population. The same *TYRP1* frameshift mutation (1104delA) observed in the original African-American patient was found to account for 50% of the mutant alleles in the study population (377). The phenotype of OCA3 in South African individuals includes red or reddish brown skin, ginger or

reddish hair, and hazel or brown irides (377–379). All of the ocular features of albinism are not always present, however, as many patients do not have iris translucency, nystagmus, strabismus, or foveal hypoplasia. Individuals who have OCA and also have red hair and reddish brown pigmented skin have been reported in Africa and in New Guinea (301,377,378,380,381), though it should be noted that some individuals with OCA1 or OCA2 also have red hair, and they should not be confused with individuals with OCA3.

The number of different *TYRP1* mutations identified in patients with OCA3 remains relatively small. Because *TYRP1* plays a role in the distal pigment eumelanin pathway, and loss of DHICA oxidase enzymatic activity does not lead to a loss but only a change in the amount or biochemical character of eumelanin (and in mouse a change in coat color), it is unsurprising that the phenotype of OCA3 is generally less clinically severe than that of OCA1, OCA2, or OCA4 (see below).

Murine *Tyrp1* is thought to encode the DHICA oxidase function of the eumelanin biosynthetic pathway (78), although human *TYRP1* does not seem to have this same catalytic function (80). DHICA is a relatively stable intermediate and, in the acidic milieu of the melanosome, its half-life is quite long. Melanogenic enzymes are present in a complex within the melanosome, sometimes termed a “metabolon” (382–385). *In vivo*, the most important role of murine and human *TYRP1* in pigment production may be its ability to stabilize tyrosinase and to act as a chaperone escort for tyrosinase trafficking to melanosomes (386). *Tyrp1* mutations significantly decrease the half-life and catalytic function of tyrosinase, which may be the major reason that *Tyrp1* and *TYRP1* mutations have dramatic effects on the pigmentation phenotype. *TYRP1* physically associates with tyrosinase during their post-translational processing, and *TYRP1* missense substitutions in the recognition of both proteins as abnormal, which leads to their retention in the ER and degradation by proteasomes (63,65). Nevertheless, in the presence of mutant *TYRP1* protein, some tyrosinase does escape the ER and is sorted to melanosomes; hence, the phenotype of OCA3 is less severe than that of OCA1. For recent reviews, see References (23,68,69).

The *TYRP1* gene consists of eight exons, with the translational start codon residing in exon 2 (101,103). *TYRP1* is a member of the tyrosinase gene family that also includes *TYR* and *DCT*. Sequences in the first exon appear to be important for the efficiency of *TYRP1* gene expression, but are not sufficient to confer pigment cell-specific expression (387). The minimum promoter of the mouse *Tyrp1* gene is between –44 and –107 bp from the transcriptional start site, located 20 bp downstream of the TATAAA box (289). Within this region, several cis-regulatory sequences, along with several regulatory factors that bind to these sequences, have been identified. As for the *TYR* promoter region,

the M-box motif appears to be a major pigment gene-specific regulatory element (388). In the mouse, MITF binds to the *Tyrp1* M-box, activating *Tyrp1* transcription, with a consequent increase in the levels of cAMP. As for the *TYR* locus, the M-box cannot be the only element to confer melanocyte-specific transcription of *TYRP1*.

Another protein, melanocyte-specific factor (MSF), may play the role of a melanocyte specific trans-activating factor, acting both as a positive-acting transcription factor and as an anti-repressor (288). MSF appears to bind to two negative regulatory elements in the *Tyrp1* promoter, one at -237, called MSEu, and the other located next to the initiation site, called MSEi (288). Both of these sites contain a 6-bp motif, GTGTGA, and bind the brachyury-related transcription factor (Tbx2), a repressor of *Tyrp1* transcription. Binding of MSF to these two elements competes with the binding of Tbx2, allowing MSF to act both as an anti-repressor and promoter of *Tyrp1* transcription (389). A complex model of *Tyrp1* transcriptional regulation includes MITF binding to the M-box, oct binding to the octamer motif, and other transcription factors binding to the TATA element (288). In this model, the presence of MSF promotes *Tyrp1* transcription. In the absence of MSF, Tbx2 binds both the MSEi and MSEu regulatory sequences, repressing *Tyrp1* transcription. This repression has been demonstrated in melanoma cells and in melanocytes. If MSF and Tbx2 also interact with the promoters of other pigment-specific genes, modulation of MSF and Tbx2 expression may be a means by which the melanocyte controls melanin pigment biosynthesis. *TYRP1* is only expressed in cells containing eumelanin, whereas *TYR* is expressed in cells containing either pheomelanin and/or eumelanin, indicating that *TYR* and *TYRP1* can also be differentially expressed, adding an additional layer of complexity to the regulation of the expression of pigment genes (113).

**145.3.2.1.4 OCA4.** Oculocutaneous albinism type 4 (OCA4; OMIM 606574) results from mutations of *SLC45A2*, the human homolog of the mouse underwhite (*uw*) gene (390). Underwhite-mutant mice manifest reduced pigmentation, so *uw* was considered a candidate gene for human OCA. After the murine *uw* gene was identified as *Slc45a2*, sequencing of the human *SLC45A2* gene in patients with OCA with no mutations in *TYR*, *OCA2*, or *TYRP1* identified a Turkish patient homozygous for a G-to-A transition in exon 2 (c.386-1 GA), resulting in a splice site mutation. A number of additional *SLC45A2* gene mutations were subsequently identified in other patients with OCA (249,270,391,392). OCA4 is the third most frequent type of OCA in the EUR population (249), and is the second most common type of OCA in Japanese (391,393), the apparent result of a founder mutation in the Japanese and Korean populations (393).

The phenotype of OCA4 is similar to that of OCA2. Individuals are often born with some hair pigment, but

this can be minimal (390-392). Hair color is white to white/yellow to blond to brown. Those with darker hair can have lightly pigmented skin that develops some tan with sun exposure. Typical ocular features of albinism are present.

The *SLC45A2* gene product, termed membrane-associated transporter protein (MATP), consists of 530 amino acids with a molecular weight of 58.3 kDa. The *SLC45A2* gene is located at chromosome 5p13.3, and consists of seven exons spanning approximately 40 kb, with two alternatively spliced transcript variants encoding different protein isoforms (394). The function of MATP is unknown, but in mouse *uw*-mutant melanocytes, tyrosinase processing and intracellular trafficking to the melanosome are disrupted and the enzyme is abnormally secreted from the cells in immature melanosomes, disrupting the normal maturation process of those organelles (395).

*SLC45A2* polymorphisms have also been associated with normal variation in human pigmentation (396). Two variant alleles, 272K and 374L, are associated with dark hair, skin, and eye color in the EUR population, and the 374L variant allele is a population marker for EUR (397).

**145.3.2.2 X-Linked Recessive Ocular Albinism.** X-linked recessive ocular albinism (OA1; Nettleship-Falls ocular albinism; OMIM 300500; Table 145-1) is an X-linked recessive disorder in which affected males manifest many of the ocular features of albinism, but in which skin and hair pigmentation is generally normal (398,399). The irides are blue to brown, and optic changes of albinism include nystagmus, reduced retinal pigment with foveal hypoplasia, altered crossing of the optic nerves at the chiasm, and variable iris transillumination (268,400-405). In African-American and Japanese males, iris color is often brown and there is little iris translucency (268,405). In EUR patients, the skin typically appears normally pigmented, whereas in African-American patients with darker skin there may be scattered hypopigmented macules; these are rarely seen in the skin of EUR individuals. The melanocytes in the skin, hair follicles, and RPE are normal in size, shape, and number, but melanocytes in the skin, hair follicles, iris and retina contain giant melanosomes (called macromelanosomes), along with some normal melanosomes (268,403,406). The systemic nature of the melanosome defect in OA1 suggests that this is really a type of OCA in which the major manifestations are in the eye.

Heterozygous females exhibit ocular pigmentation changes that result from X-inactivation (401,407-410). A variegated or spotty pattern of retinal pigmentation (sometimes described as a mud-splattered mosaic pattern), which progressively becomes more coarse, and punctate areas of iris translucency are seen in 80-90% of obligate heterozygous females (401,410). Macromelanosomes are seen in the melanocytes of obligate

heterozygous females. A few heterozygous females have more evident ocular changes of albinism, including nystagmus and reduced visual acuity, and these are thought to be the result of non-random X-inactivation (411).

The gene for OA1 was initially localized to the short arm of the X chromosome in linkage with the Xg blood group, and was subsequently localized to Xp22.32 (412,413) and then more precisely to Xp22.3–Xp22.2, between the markers DXS237 and DXS143 (414). The OA1 gene was subsequently identified as *GPR143* (415,416), encoding G protein-coupled receptor 143. The coding sequence consists of nine exons and encodes a 404 amino acid protein that has several possible transmembrane domains, possibly with multiple isoforms (417). The mouse *Gpr143* gene encodes a protein with a high degree of similarity to the human protein, including the presence of isoforms (418).

OA1 mutations consist of missense, frameshift, and splicing mutations, as well as a number of different deletions involving all or part of the *GPR143* locus (419–428). Many of these deletions involve exon 2, most likely caused by unequal crossing-over between flanking *Alu* repeats (two *Alu* repeats in intron 1 and one *Alu* repeat in intron 2) (426,429). Other exons are also involved in deletions (419,427), and the frequency of large intragenic deletions is higher in Northern American than in European cases that have been studied (419). The missense mutations are located throughout the central coding region with some clustering between the first and second transmembrane regions in exons 1, 2, and 3. Some individuals with missense mutations also have other features, including X-linked ichthyosis and developmental delay (427).

The GPR143 protein is thought to be associated with the melanosome membrane in the melanocyte (417). GPR143 is a G protein-coupled receptor, representing a novel member of the GPCR superfamily, and has specific interactions with heterotrimeric G proteins (430). OA1 may therefore be caused by a defect in an intracellular signal transduction system. The gene is expressed at high levels in the retinal pigment epithelium and at lower levels in the brain and adrenal glands. Part of the pathogenesis of OA1 is the formation of giant macromelanosomes in melanocytes. Analysis of *Gpr143*-knockout mice suggests that the macromelanosomes are produced by the abnormal growth of individual melanosomes, instead of fusion of several smaller melanosomes (431). The GPR143 protein may be involved in sorting or trafficking the vesicles to developing melanosomes (432,433), with a role in reorganization of the late endosomal compartment, including enlargement of the late endosomes and a redistribution of the mannose 6-phosphate receptors as important steps in melanosome biogenesis (433). GPR143 may function as a stop signal for melanosome growth, its absence resulting in macromelanosome formation. In some respects, OA1 may thus be considered

a defect of melanosome biogenesis/maturation (see below).

One large Afrikaner family has been reported with X-linked OA co-segregating with late-onset sensorineural deafness (434). Macromelanosomes were demonstrated in skin from affected males and obligate heterozygous females, and the clinical features were consistent with OA1. The locus for this condition maps to chromosome Xp22.3, suggesting overlap with OA1 (434,435), and it is unclear whether this OA-deafness phenotype is part of the OA1 spectrum or is related to a contiguous gene defect in this family. A family that contained three generations of males and females affected with congenital deafness and OA has been described, but little information on this family is available (436).

**145.3.2.3 Autosomal Dominant OCA.** “Autosomal dominant OCA” has been described in several families (437,438). One French family had hypopigmentation in three generations, including one family member with hypopigmentation and PWS (438), suggestive of OCA2. Indeed, all families with multigenerational OCA that have been subjected to molecular analysis have proven to be examples of pseudodominance, with mutations of *TYR* or *OCA2* involving affected individuals in sequential generations.

#### 145.3.2.4 Other OCA Candidate Genes.

**145.3.2.4.1 PMEL.** In mice, *Pmel* corresponds to the silver (*si*) locus, and in humans is located at chromosome 12pter–q21 (439). The *PMEL* gene encodes a 668 amino acid protein (known as Pmel17, GP100, and silver) with molecular weight of 70.9 kDa including the putative signal peptide. The protein has several potential glycosylation sites and a hydrophobic region at the carboxyl-terminal end, indicating that it may be membrane bound. Pmel17 protein was initially characterized as “stablin” (440), which was shown by transfection experiments to be associated with “indole-blocking factor” or “stablin” activity, which binds DHICA and DHI (440), associated with polymerization of melanogenic intermediates (441,442). Pmel17 is a relatively abundant matrix component of both melanosomes and premelanosomes (36,61,443), with extensive sequence similarity to a chicken melanosomal matrix protein (444,445). The Pmel17 protein may function as a component of the melanosomal matrix, limiting melanogenesis to that intracellular compartment and perhaps protecting melanocytes from harmful intermediates of melanin biosynthesis (79). In that respect, Pmel17 functions as a solid-state surface for melanin binding and polymerization, fulfilling the polymerase function ascribed to it (23,442,446,447).

In the mouse, *si* mutations are characterized by premature graying (“silvering”) of coat hair due to melanocyte loss (79). *Si*-mutant melanocytes grown in culture produce pigment but have a much slower growth rate than normal melanocytes (448).

The Pmel17 protein has also been identified as a melanoma-specific antigen. The melanoma-specific antibody, HMB50, recognizes a glycoprotein released by neonatal foreskin melanocytes and by melanoma cells but not by adult melanocytes, independent of the amount of pigment produced by the cells (449). It was hypothesized that the protein related to the proliferative state of the cells, with only growing cells producing the molecule, thus correlating with *si* mutations that affect melanocyte viability and cause premature graying. It was subsequently shown that the protein recognized by HMB50 is Pmel17 (450,451). Human Pmel17 was also isolated as a melanocyte lineage-specific antigen (gp100) (452) recognized as a melanoma antigen by a cultured T-cell line established from the tumor-infiltrating lymphocytes (TILs) of a patient with advanced metastatic melanoma (453). It has been suggested that Pmel17/gp100 may be a tumor-rejection antigen that could be useful for the development of immunotherapy for melanoma (453).

*PMEL* has been screened as a candidate gene in OCA and AROA patients who lack mutations in *TYR*, *OCA2*, *TYRP1*, and *SLC45A2* (249,270). However, thus far no apparently pathological *PMEL* mutations have been identified.

**145.3.2.4.2 DCT.** The *DCT* gene, which encodes DOPachrome tautomerase, is located at chromosome 13q32.1. *DCT* mutations have not yet been associated with pigmentary disease in humans; however, given the relatively minor effects on pigmentation of *Dct* mutations in mice and its specific function in the melanogenic pathway, it might be expected to be involved with a very mild form of OCA. DOPachrome tautomerase converts DOPachrome to its carboxylated derivative DHICA; in the absence of this enzyme, DOPachrome will be spontaneously decarboxylated to produce DHI, which dramatically affects the properties of the melanosomes produced. Although the metal-binding domains found in tyrosinase are conserved in *DCT*, copper is not the bound ligand, and zinc fulfills the role as the active metal ligand, consistent with the distinctly different reactions catalyzed by tyrosinase and *DCT* (59). The size of *DCT* (about 75–80 kDa) is slightly larger than tyrosinase or *TYRP1*. Expression of *DCT* during development occurs earlier than does expression of *TYR* and *TYRP1*; the implications of this are not known, but have been suggested to perhaps relate to its role in minimizing the cytotoxicity of melanogenic intermediates. The production of DHICA rather than DHI may have cytotoxic implications to melanocytes (454); DHI is relatively cytotoxic *in vivo* because it is quickly metabolized to indole-5,6-quinone and then to melanin. The production of DHICA rather than DHI may be of primary importance in minimizing the cytotoxic effects of melanogenic intermediates, rather than the nature and color of melanin per se. For recent reviews, see References (23,68,69).

## 145.4 DISORDERS OF MELANOSOME BIOGENESIS/TRANSPORT—HERMANSKY-PUDLAK SYNDROME, CHÉDIAK-HIGASHI SYNDROME, AND GRISCELLI SYNDROME

### 145.4.1 Hermansky–Pudlak Syndrome (HPS)

Hermansky–Pudlak syndrome (HPS; (455–457)) is a group of rare autosomal recessive genetic disorders characterized by OCA of variable severity (221,458–460), a bleeding diathesis, and a poorly defined ceroid-lipofuscin lysosomal storage disease (Figure 145-7). Most patients develop life-threatening complications during adulthood, including progressive pulmonary fibrosis, granulomatous colitis, and occasionally cardiomyopathy and renal failure (456,457,459,461–463). Unlike in CHS and Griscelli syndrome, discussed below, there is no immune deficit in HPS (464). There is currently no specific or effective treatment for HPS, and average survival is only 30–50 years, death usually resulting from restrictive lung disease (68%), hemorrhage (17%), or colitis (15%). HPS is rare in most populations, but is relatively common in Puerto Rico, where the prevalence has been estimated at approximately 1 in 1800 (456,465).

In HPS, skin hypopigmentation is associated with quantitatively reduced and qualitatively abnormal melanosomes in skin melanocytes (466,467). Bleeding is usually clinically mild, and is associated with virtual absence of platelet dense granules, “storage pool deficiency,” and defective platelet aggregation (456,468–470). Lysosomal

**FIGURE 145-7** A Puerto Rican patient with HPS1.

storage in HPS is characterized by accumulation of ceroid-lipofuscin-like material in the lysosomes of reticuloendothelial cells, bone marrow, lung macrophages, and many other cell types (456,463,471–474), suggesting lysosomal dysfunction. However, HPS patients exhibit none of the other typical findings of lysosomal storage disease.

In the mouse, there are 15 loci that, when mutated, result in phenotypes similar to that of human HPS (see Table 145-1), including hypopigmentation due to a reduction of melanosomes; platelets with an absence of dense bodies, which results in a prolonged bleeding time; and ceroid deposition in a number of organ tissues (475–477). Most of the protein products of these loci appear to be involved in protein sorting and trafficking, resulting in abnormal biogenesis of lysosome-related organelles, including melanosomes, platelet dense bodies, and type II pneumocytes (460,478–481).

The identification of these mouse loci with HPS-like phenotypes has facilitated the identification of human genes associated with other types of HPS, although the first HPS gene was identified in humans by use of labor-intensive positional cloning techniques (482). As these HPS genes have been identified, a common theme has emerged; all of the corresponding proteins are involved in the formation of lysosomes and other related organelles, including melanosomes (47). Furthermore, all of these HPS genes are ubiquitously expressed in humans and in mice. Three genes—*AP3B1* (encoding the  $\beta$  subunit of adaptor protein 3 complex; APC-3); *AP3D1* (encoding the  $\delta$  subunit of APC-3); and *VPS33A* (encoding vacuolar protein sorting protein 33a; VPS33A) have orthologs in yeast. APC-3 is a protein complex involved in protein trafficking of integral membrane proteins from the trans-Golgi network or late endosomes (460). VPS33A is involved in vacuolar protein sorting (483). In contrast, the other HPS proteins do not have orthologs in yeast and have no significant homology to other proteins (50,479). These other HPS proteins form protein complexes termed biogenesis of lysosome-related organelles complexes (BLOCs). There are at least three such BLOC complexes, BLOC-1, BLOC-2, and BLOC-3, ranging in size from from 175 kDa (BLOC-3) to 340 kDa (BLOC-2) (50,479,484,485). These complexes contain different numbers of proteins, with BLOC-1 containing at least eight protein subunits (50). The exact functions of the BLOCs remain unknown, but they most likely are involved in the fusion events involving endosomal membranes and organelle biogenesis. In the mouse, mutations involving protein subunits of BLOC-1 have more severe phenotypes than BLOC-2 or BLOC-3, suggesting that BLOC-1 may be involved in early events in melanosome formation. However, this is less evident in humans. There are reports of other BLOCs (BLOC-4 and BLOC-5), but these may be alternatives to BLOCs 1–3.

There are currently nine human HPS genes known, all of which are homologous to these mouse HPS-like loci. *HPS1* is the human homolog of mouse pale ear (*ep*) (482,484,486–489). *AP3B1* (HPS2) is the human homolog of mouse pearl (*pe*) (490–492). *HPS3* is the human homolog of mouse cocoa (*coa*) (493–495). *HPS4* is the human homolog of mouse light ear (*le*) (484,496). *HPS5* is the human homolog of mouse ruby-eye 2 (*ru2*) (497). *HPS6* is the human homolog of mouse ruby-eye (*ru*). *DTNBP1* (HPS7) is the human homolog of mouse sandy (*sd*) (498). *BLOC1S3* (HPS8) is the human homolog of mouse reduced pigmentation (*rp*) (499,500). *PLDN* (HPS9) is the human homolog of mouse pallid (*pa*) (501).

**145.4.1.1 HPS1.** HPS is generally rare. However, two isolated populations in which Hermansky–Pudlak syndrome type 1 (HPS1; OMIM 203300) is frequent—one in Puerto Rico (Figure 145-7) and the other in Switzerland (502)—provided an opportunity to map the first HPS gene, *HPS1* (OMIM 604982) to chromosome 10q24.2 (489,502,503), on the assumption of autozygosity based on a hypothesized common founder for the mutated gene in these two population isolates. *HPS1* was mapped a chromosome region syntenic to that containing the pale ear (*ep*) and ruby-eye (*ru*) loci of the mouse, two of the candidate HPS models. Further fine mapping, subsequent isolation of the *HPS1* gene, and DNA sequencing led to identification of pathological gene mutations (482). Furthermore, *HPS1* was found to be orthologous to the mouse pale-ear (*ep*) (482,487,504) gene. The human *HPS1* gene consists of 20 exons spanning 30.5 kb (486). A partial *HPS1* pseudogene comprised of exon 6 is located on chromosome 22q12.2–12.3 (505). The major 3.6 kb *HPS1* mRNA encodes a 700 amino acid, 79.3 kDa protein (482,486). A minor 1.5 kb mRNA encoding a 324-amino acid protein results from alternative splicing (488). The 3.6 kb mRNA encodes an HPS1 polypeptide containing two transmembrane domains, whereas the HPS1 protein encoded by the 1.5 kb mRNA lacks the carboxyl transmembrane domain. Confocal immunofluorescence analysis shows both cytoplasmic and membrane-associated distributions of HPS1 protein (485,506), suggesting the possible existence of soluble and insoluble isoforms, as would be predicted by the two alternative HPS1 polypeptides (476). Primer extension analysis identified a single major transcription start site and two minor sites (486). There are two TATA boxes, with the proximal site most likely being the active one. Several other putative transcriptional motifs occur in this area, but none are melanocyte-specific (486).

A founder 16-bp duplication frameshift mutation occurs in Puerto Rican HPS1 patients, and a 1-bp duplication frameshift was found in the Swiss HPS1 patients (482). Many other *HPS1* mutations have been identified, most of which constitute protein-null alleles (458,475,482,507–511). Among the most

important *HPS1* mutations is a splice consensus mutation (IVS5+5 GA) (507) that is common in Japan and appears to derive from an ancestral founder (510,511).

Several tissues are affected by *HPS1* mutations, and *HPS1* mRNA is expressed in a number of different cell types (482), including melanocytes, megakaryocytes (progenitors of platelets), and several other tissues, including kidney, liver, and lung, the sites of ceroid accumulation in patients with HPS. The HPS1 protein is a component of the BLOC-3 protein complex which is important for protein trafficking, although the precise mechanism is not yet defined (484,485).

**145.4.1.2 HPS2.** Two individuals of Dutch origin who showed clinically more severe symptoms than typical HPS1, including the usual features of OCA and bleeding together with additional features of neutropenia and immune deficiency, were identified who did not have a detectable mutation in HPS1. It was therefore hypothesized that these individuals had a mutation in another locus. Mutations in the human ortholog of the mouse pearl (*pe*) gene (491), *AP3B1*, located at chromosome 5q14.1, encoding the  $\beta$ 3A subunit of adaptor complex AP-3, were found to be responsible for HPS2 (OMIM 608233) in these individuals (491,512), and additional cases were identified subsequently (513,514). Fibroblasts from these patients had normal messenger RNA (mRNA) levels for all four AP-3 subunits,  $\delta$ ,  $\beta$ 3A, 3A, and  $\alpha$ 3, but had lower protein levels when compared to normal fibroblasts or individuals with mutations in *HPS1*. The clinical severity of the HPS2 phenotype roughly correlates with the mutations that are present (515).

AP-3 is critical for protein trafficking (492,516,517), including targeting tyrosinase to melanosomes (518), and functions with AP-1, BLOC-2, RAB38, and RAB32 to mediate protein trafficking to lysosome-related organelles (519).

**145.4.1.3 HPS3.** HPS3 (OMIM 614072) results from mutations in *HPS3* (493), the human ortholog of the mouse cocoa (*coa*) (495) gene, located at chromosome 3q24. HPS3 was initially described in a Puerto Rican isolate (493) and subsequently has been identified in individuals from a variety of other populations (520). A founder mutation (3904-bp deletion of exon 1 and adjacent intron) was identified in the Puerto Rican isolate (465,493), and has subsequently been identified in patients from other groups (520). The HPS3 phenotype is somewhat less severe than that of HPS1, with less hypopigmentation, less severe ocular features, and less bleeding, and may not include the complication of pulmonary fibrosis (520,521). It is of interest that prevalence of two different forms of a disorder as rare as HPS occurs in Puerto Rico, suggestive of possible heterozygote advantage, though this has not yet been proven. *HPS3* encodes a component of the BLOC-2 complex (493–495).

**145.4.1.4 HPS4.** HPS4 (OMIM 614073) results from mutations in *HPS4*, the human ortholog of the mouse

light ear (*le*) (496) gene, located on chromosome 22q12.1. HPS4 is perhaps the second most common form of HPS in EUR individuals (496,522,523). HPS4 is clinically similar to HPS1, with an OCA phenotype generally similar to that of OCA1.

The *HPS4* gene encodes a 708 amino acid, 76.9 kDa polypeptide. It is a component of the BLOC-3 complex (484,485,524) and interacts with RAB9 (525).

**145.4.1.5 HPS5.** HPS5 (OMIM 614074) results from mutations in the *HPS5* gene, which consists of 23 exons located at chromosome 11p15.1. The initial patient, born to consanguineous Turkish parents, was homozygous for a 4-bp frameshift deletion (497). *HPS5* is the human ortholog of the mouse ruby-eye-2 (*ru2*) (497) and *Drosophila* pink (*p*) (526,527) genes, and encodes a member of the BLOC-2 complex (497). The 1129 amino acid HPS5 polypeptide contains a number of predicted phosphorylation sites for protein kinases A and C and casein kinase II, and a predicted myristoylation site, and binds to  $\alpha$ -integrin chains.

**145.4.1.6 HPS6.** HPS6 (OMIM 614075) results from mutations in the *HPS6* gene, which consists of a single exon located at chromosome 10q24.32, and is the human orthologue of the mouse ruby-eye (*ru*) (497) gene. A number of gene mutations have now been identified in different patients with HPS6 (497,528,529). The 775 amino acid HPS6 protein is a component of the BLOC-2 complex (497).

**145.4.1.7 HPS7.** HPS7 (OMIM 614076) results from mutations in *DTNBP1*, located at chromosome 6p22.3, and is the human ortholog of the mouse sandy (*sdv*) (498) gene. *DTNBP1* has also been genetically associated with susceptibility to schizophrenia (530), although findings have been inconsistent (531,532). The original HPS7 patient, an adult female born of consanguineous parents, was homozygous for a nonsense mutation, and had typical HPS with no psychiatric symptoms. The 352 amino acid, 40 kDa gene product is named dystrobrevin-binding protein 1 (also dysbindin) (533) and is a component of the BLOC-1 complex (498).

**145.4.1.8 HPS8.** HPS8 (OMIM 614077) results from mutation in *BLOC1S3*, located at chromosome 19q13.32 (499) and is the human ortholog of the mouse reduced pigmentation (*rp*) (500) gene. Homozygous mutations were identified in members of a large, inbred Pakistani family with OCA but inconsistent history of bleeding diathesis (499). *BLOC1S3* is a component of the BLOC-1 complex (534).

**145.4.1.9 HPS9.** HPS9 (OMIM 614171) results from mutations in *PLDN*, located at chromosome 15q21.1 (501), and is the human ortholog of the mouse pallid (*pa*) gene. An Indian child born of consanguineous parents was homozygous for a nonsense mutation. *PLDN* encodes pallidin, a 172-amino acid protein that is a component of the BLOC-1 complex (535,536). *PLDN* consists of seven exons, subject to alternative mRNA

splicing that results in two somewhat different protein isoforms, PLDN-1 and PLDN-2 (501).

### 145.4.2 Chédiak–Higashi Syndrome

Chédiak–Higashi syndrome (CHS; OMIM 214500) is a rare autosomal recessive disorder that consists of OCA, immune defects with neutropenia and susceptibility to recurrent bacterial infections, mild bleeding diathesis, and progressive neurological abnormalities; for reviews, see (537,538). Skin, hair, and eye pigment is reduced or diluted in CHS, but some affected individuals do not exhibit obvious albinism and the hypopigmentation may only be noted when compared to other family members. Hair color is light brown to blond, with a metallic silver-gray sheen. Iris pigment is reduced, and nystagmus and photophobia may be present or absent (539). Most patients with CHS eventually develop an “accelerated” lymphoproliferative phase, with generalized lymphohistiocytic infiltrates with erythrophagocytosis (540), fever, jaundice, hepatosplenomegaly, lymphadenopathy, pancytopenia and bleeding. There is no specific treatment for CHS, and management of the accelerated phase is quite difficult. Chemotherapy provides only transient benefit, and most patients die prior to seven years of age unless given bone marrow transplantation (541–543), though this does not correct the hypopigmentation and does not prevent eventual neurological deterioration (542).

About 5–15% of CHS patients have a milder clinical course, with less severe hypopigmentation, fewer significant infections, and no accelerated phase. Most of these patients eventually develop neurological manifestations, including seizures, modest progressive intellectual decline, and progressive peripheral neuropathy, with tremor, muscle weakness, clumsiness and wide-based gait (537,544,545).

The ultrastructural hallmark of CHS is the presence of large eosinophilic peroxidase-positive inclusion bodies in granulocytes and other tissues (546). The diagnosis of CHS is thus readily established on clinical grounds together with examination of leukocytes in a standard peripheral blood smear (Figure 145-8), and indeed sometimes is diagnosed incidentally on this basis.

The gene for CHS was localized to chromosome 1q42.3 by homozygosity mapping (547,548). At the same time, the gene (named *Lyst*) for a similar murine phenotype, beige (*bg*), was identified and the homologous human *LYST* (also called *CHS1*) gene was mapped to chromosome 1q43 using mouse *Lyst* as a hybridization probe (549,550). The human *LYST* gene was subsequently cloned and sequenced, and mutations were identified in individuals with CHS (551–553). A large number of *LYST* mutations have now been identified (554–556), and there is a clear genotype–phenotype correlation, with patients with typical, severe CHS being homozygous for protein-null alleles and patients with milder forms of CHS being compound heterozygotes or

**FIGURE 145-8** Prominent cytoplasmic inclusions in a polymorphonuclear leukocyte in a patient with Chediak–Higashi syndrome.

homozygotes for alleles containing missense mutations (555).

The human *LYST* gene expresses two transcripts, a major 13-kb mRNA that encodes the major 3801 amino acid, 429kDa *LYST* protein and a minor 6-kb mRNA that encodes a 1990 amino acid polypeptide (551,552,557). *LYST* mRNA is ubiquitously expressed in all cells and tissues tested in both in humans and in mice, and alternative splicing produces transcripts ranging from 3–4kb to 12–14kb in size (551,552). The major *LYST* protein contains a stathmin-like sequence as well as several HEAT, ARM, and WD40 repeats (551,552). The HEAT and WD40 repeats are associated with proteins involved with vesicle trafficking and protein transport (558). *LYST* also contains a so-called BEACH (Beige and CHs) domain (552). Immunohistochemistry analysis shows that the *LYST* protein is cytosolic, with no apparent membrane association (550,559). The specific function of the *LYST* protein is not known, but it is thought to be a lysosomal trafficking regulator (*LYST*), perhaps accounting for the abnormal trafficking of melanogenic proteins found in melanocytes from individuals with CHS (551,556,560,561).

### 145.4.3 Griscelli Syndrome

Griscelli syndrome (GS) is associated with pigment dilution of the skin and the hair, with large clumps of pigment in hair shafts and accumulation of melanosomes in melanocytes (562). Most patients also develop an uncontrolled T-lymphocyte and macrophage activation syndrome (known as hemophagocytic syndrome), leading to death in the absence of bone-marrow transplantation (562).

Griscelli and colleagues initially reported two girls with hypopigmentation characterized as silver-gray hair and scattered hypopigmented areas surrounded by normal or hyperpigmented skin (563). No ocular features of albinism were present, even though the term partial albinism was used in the title of the paper. Both had neutropenia, thrombocytopenia, absent delayed hypersensitivity and hypogammaglobulinemia with repeated infections, and one died with sepsis. Parents and sibs were normal, and inheritance appeared to be autosomal

recessive. Melanin was irregularly distributed in the skin. Melanocyte number and size were normal. Melanocytes were full of normal-sized pigmented melanosomes, but only a few were passed to keratinocytes. Hair shafts contained large clumps of pigment, primarily in the medullar zone, interspersed with normal-sized pigment granules, and these produced the silver-gray sheen.

There are now three types of GS (for review, see Reference (44) and see Table 145-1), all of which include hypopigmentation (“hypomelanosis”) of the skin and hair, with large clumps of pigment granules in the hair shafts and an accumulation of melanosomes in cutaneous melanocytes, due to defects of melanosome transport and inability to distribute melanosomes to keratinocytes in the hair shafts and skin (564). Clinical manifestations other than melanosome clumping and hypopigmentation include a primary neurological deficit (GS1), immune impairment (GS2), or solely hypopigmentation of the skin and hair (GS3). The two original GS patients are now classified as having GS2.

**145.4.3.1 GS1.** Griscelli syndrome type 1 (GS1; OMIM 214450) results from mutations in *MYO5A* (565); reviewed in References (44,45,564). *MYO5A* consists of 35 exons located on chromosome 15q21.2. *MYO5A* is the human ortholog of the mouse dilute (*d*) gene. GS1 is characterized by hypopigmentation and a primary neurological abnormality but does not include immunological deficiencies or hemophagocytic syndrome manifestations (566). Neurological impairment can be marked early in life, with hypotonia, seizures, motor delay, and mental retardation (565,567–571). Similar cases have been described as Elejalde syndrome (OMIM 256710) (572–574). *MYO5A* encodes myosin 5A, a dimeric 160 kDa protein containing an actin-binding domain and an ATP-binding site, which is involved in short-range movement of melanosomes along actin filaments. Together with *RAB27A* and *MLPH*, *MYO5A* plays a role in moving melanosomes to the dendrites.

**145.4.3.2 GS2.** Griscelli syndrome type 2 (GS2; OMIM 607624) results from mutations in *RAB27A* (562,575–578); reviewed in References (44,45,564). *RAB27A* consists of six to nine exons, depending on alternatively mRNA splicing, located on chromosome 15q21.3. *RAB27A* is the human ortholog of the mouse ashen (*ash*) gene. GS2 is characterized clinically by hypopigmentation and an immune deficiency (562,575–578). Affected individuals develop a hemophagocytic syndrome similar to that in CHS, with secondary T-lymphocyte and macrophage activation that leads to lymphohistiocytic infiltration of the central nervous system (576,579), and most patients will die unless treated by bone marrow or stem cell transplantation (579,580). *RAB27A* is a GTPase and part of the Ras oncogene family. *RAB27A* acts as a *MYO5A* receptor and functions as part of a molecular motor complex required for the movement of melanosomes from the perinuclear area to the dendrites, which is

necessary for their eventual transfer to neighboring keratinocytes (334).

**145.4.3.3 GS3.** Griscelli syndrome type 3 (GS3; OMIM 609227) results from mutations in *MLPH* (581,582); reviewed in References (44,45,564). *MLPH* consists of 16 exons (15 coding exons) located on chromosome 2q37, and is the human orthologue of the mouse leaden (*ln*) gene. GS3 is characterized clinically by hypopigmentation without neurological or immunological problems (583). *MLPH* is also involved in melanosome movement, perhaps functioning to tether melanosomes to the myosin motor transport complex containing *MYO5A* (581).

## 145.4.4 Rare Conditions with Albinism and Hypopigmentation

**145.4.4.1 Generalized Cutaneous Hypopigmentation (Albinoidism).** The term albinoidism refers to generalized cutaneous hypopigmentation in the absence of ocular changes of albinism (OMIM 126070) (584). This is not a very precise term, and it is confusing because of its similarity to the term albinism, and probably has no place in the modern clinical lexicon; a more correct term would be generalized cutaneous hypopigmentation. Families with generalized cutaneous hypopigmentation have been described, and have the potential of representing new genetically distinct syndromes.

**145.4.4.2 Oculocerebral Syndrome with Hypopigmentation (Cross Syndrome).** Cross syndrome presents with generalized cutaneous hypopigmentation and neurological abnormalities that include developmental delay, mental retardation, spasticity, athetoid movements, muscle atrophy, growth retardation and other changes (OMIM 257800) (585–587). The features of this syndrome are variable, and all cases may not represent the same entity. The cutaneous hypopigmentation has been generalized but variable in degree, and the hair has been noted to have a white, silver, or silver-gray appearance (588,589). Some of the affected individuals have had ocular changes of albinism, suggesting a diagnosis of OCA1 or OCA2 rather than hypopigmentation limited to the hair and skin (590).

## 145.5 DISORDERS OF MELANOCYTE SURVIVAL—VITILIGO

Acquired loss of integumentary melanocytes is termed vitiligo, one of the most striking of all human disease phenotypes, and perhaps the most common pigmentary disorder. Vitiligo is characterized clinically by patchy loss of pigmentation of the skin and overlying hair, in most cases with tendency towards a somewhat symmetrical distribution (Figure 145-9). In some respects, vitiligo appears similar to piebaldism, and many patients with piebaldism are initially misdiagnosed as vitiligo. The marked contrast between patches of involved and uninvolved skin particularly impacts persons of color,

with social consequent stigmatization and negative impact on quality of life (591). Indeed, the first Prime Minister of India, Jawaharlal Nehru, ranked vitiligo with malaria and leprosy as the principal medical “curses” of his country.

There are two main types of vitiligo: generalized vitiligo (GV; includes non-segmental vitiligo, acrofacial vitiligo, vitiligo universalis; Figure 145-9) and segmental vitiligo (SV) (592–595). In GV, which represents approximately 90% of cases, depigmentation tends to be slowly progressive, waxing and waning but sometimes eventually involving virtually the entire integument. In SV, depigmentation tends to have rapid onset, but then stabilizes and remains quite localized. In both GV and SV, involved areas of skin generally lack melanocytes (596). It is now clear that GV is an autoimmune disease, and while SV has been much less studied, there is some recent evidence that it may also have an autoimmune basis that for some reason only acts locally.

### 145.5.1 Generalized Vitiligo (GV)

GV accounts for >90% of cases of vitiligo, is usually adult-onset ( $23.9 \pm 16.0$  years), is progressive and multifocal. In about 30% of cases, GV co-occurs with other autoimmune disorders, particularly autoimmune thyroid disease, type 1 diabetes, rheumatoid arthritis, pernicious anemia, psoriasis, Addison’s disease and lupus, both in GV patients themselves and in close family members (597,598), suggesting that these disorders share common genetic risk factors. There is extensive evidence that GV has an autoimmune pathogenesis (for review, see Reference (599)), including its co-occurrence with other autoimmune diseases, the frequent occurrence of new lesions at sites of skin injury (“Koebner phenomenon”), autoantibodies to melanocyte components in some patients (600), and perilesional infiltrates of cytotoxic T-lymphocytes (601).

The occurrence of frequent clustering of GV cases among close relatives (602,603) was initially interpreted as suggesting autosomal dominant inheritance (592). However, it is now clear that GV is in most cases a complex, polygenic, multifactorial disorder, involving numerous different susceptibility genes, most encoding proteins that regulate or mediate recognition or destruction of melanocytes by the immune system, as well as unknown environmental triggers (35,604,605). Many GV susceptibility loci are shared with other autoimmune diseases, most the human ortholog of likely underlying the observed epidemiological association among these diseases.

One family has been identified in which GV exhibits a pattern of autosomal dominant inheritance with reduced penetrance (606), suggestive of a rare causal variant with high penetrance. Genetic linkage analysis was used to map this locus (AIS1) to chromosome 1p31.3 (OMIM 607836) (606), and fine-mapping and DNA sequencing subsequently identified a private mutation in the promoter of *FOXD3* in affected family members that

**FIGURE 145-9** A patient of African-derived origin with generalized vitiligo.

up-regulated transcription in cells that express endogenous *FOXD3* mRNA (607). The *FOXD3* protein is an embryonic transcription factor essential for neural crest development and specification of the melanoblast lineage, and mutations that up-regulate its functions cause hypopigmentation (608–612).

Genetic linkage analysis has also been used to study families with more typical GV in the EUR and Chinese populations. Linkage analysis of EUR multiplex GV families identified *NLRP1* (613,614), encoding a key regulator of the innate immune system, particularly in skin dendritic (Langerhans) cells (615). Genetic linkage analysis of Chinese multiplex GV families identified the MHC (OMIM 193200) (616); *XBP1* on chromosome 22q12 (616,617), encoding a transcription factor which regulates transcription of MHC class II alleles (618,619); as well as a locus on chromosome 4q13–q21 that has not yet been identified (620).

Genome-wide association studies (GWAS) have also been used to identify GV susceptibility loci. In EUR subjects, two GWAS (621–624) have identified at least 29 loci, including *PTPN22*, *RERE*, *IFIH1*, *FOXP1*, *CD80*, *LPP*, *CLNK*, *TSLP*, *HLA-A*, *MHC class II* (the specific gene has not yet been identified), *BACH2*, *CCR6*, *SLA*, *IL2RA*, *CASP7*, *CD44*, *TYR*, an unknown locus on chromosome 11q21, *IKZF4*, *SH2B3*, *GZMB*, *OCA2*, *MC1R*, *UBASH3A*, *C1QTNF6*, *TOB2*, *FOXP3*, probably *TICAM1*, and have confirmed *XBP1*, altogether accounting for about 18 percent of the heritability of GV in EUR individuals (624). In Chinese subjects, a GWAS (625) identified two loci; the MHC class III region and *CCR6*. All but three of these GV susceptibility genes

encode proteins involved in regulation of the immune system and/or have been genetically associated with susceptibility to other autoimmune diseases. However, these three encode melanocyte components: *TYR* encodes tyrosinase; *OCA2* encodes the OCA2 protein; and *MC1R* encodes the melanocortin receptor. Each of these genes has been associated with normal pigmentary variation of the skin, hair, or eyes. For *TYR*, DNA sequencing has identified the causal (protective) variants as two missense substitutions common in the EUR population but virtually absent in other groups, S192Y and R402Q (626). For *OCA2*, the causal (protective) variant appears to be the same as that which is associated with blue eyes in the EUR population (624). In both cases, these GV-protective variants likely reduce the amount of the corresponding *TYR* or *OCA2* peptide antigens available for presentation by HLA-A2 (for which the causal allele has been identified as *HLA-A\*02:01*) (626). Furthermore, for both *TYR* and *OCA2*, the variants that are protective for GV are likewise high-risk for malignant melanoma (621,626). For these loci, GV and melanoma are thus genetic opposites, suggesting that GV may represent a dysregulated normal process of immune surveillance for malignant melanoma (627).

### 145.5.2 Segmental Vitiligo (SV)

SV usually occurs in childhood (up to 30% of pediatric vitiligo), and has rapid onset but remains localized and unilateral, often on the face (593,594,628). SV is not epidemiologically associated with co-occurrence of the autoimmune diseases that are associated with GV (595). Nevertheless, some evidence has recently emerged that immune phenomena may contribute to the pathogenesis of SV (629), including observation of a lymphocytic infiltrate of CD8+ and some CD4+ T cells at the lesional margin (630). Furthermore, GV and SV occasionally co-occur in the same families (595), suggesting that they may share some causal risk factors. As yet, there has been no systematic analysis of the genetic basis of SV.

### ACKNOWLEDGMENT

The authors wish to acknowledge the previous contributions of Richard A King, William S Oetting, C Gail Summers and Donnell J Creel, who wrote earlier versions of this Chapter, upon which much of this is based. This work was supported in part by the Intramural Research Program of the National Cancer Institute at NIH, and by NIH grants AR045584 and AR056292.

### Biographies

**Dr Richard A Spritz** is Professor of Pediatrics and Director of the Human Medical Genetics and Genomics Program at the University of Colorado School of Medicine. Dr Spritz's work in the field of human genetics began in the "pre-molecular" era, and in the mid-1970s he took part in the earliest work on recombinant DNA and human genes, including the first cloning of human genes and identification of the first human disease gene mutation. Over the past 30 years, Dr Spritz and his colleagues have studied the genes involved in causing many different human diseases, including hemoglobin disorders, albinism, piebaldism, Hermansky–Pudlak syndrome, Chediak–Higashi syndrome, and other skin diseases, autoimmune diseases such as vitiligo and thyroid disease, and cleft lip/palate, and he has published over 225 scientific papers on these investigations. For the past several years, Dr Spritz has led an international team that carried out genomewide association studies of generalized vitiligo, establishing the autoimmune basis of the disease and its inverse relationship with malignant melanoma.

**Dr Vincent J Hearing** obtained his PhD from the Catholic University of America and continued his studies on mammalian pigmentation initially as a postdoctoral fellow, then as a staff fellow in the Dermatology Branch at the NCI, moving to the Laboratory of Cell Biology in 1983 where he now is a Senior Biomedical Research Scientist. He has served as President of the PanAmerican Society for Pigment Cell Research, President of the International Federation of Pigment Cell Societies, Editor of the journal *Pigment Cell Research* and Organizer of the 19th International Pigment Cell Conference. He serves as Deputy Chief of the Laboratory of Cell Biology and Chief of the Pigment Biology Section at the NCI, where he continues his research.

This article is a revision of the previous edition article by Howard P Baden, volume 3, pp 3428–3448, © 2007, Elsevier Ltd.

### 146.1 INTRODUCTION

Ichthyosis, derived from the Greek word meaning fish, is a descriptive name for a group of inherited disorders of keratinization (cornification) in which the skin has large amounts of scale. Most of these patients have one of four major types of ichthyosis (see Table 146-1), the remainder fall into several less common forms.

### 146.2 APPROACH TO DIAGNOSIS OF ICHTHYOSIS

Ichthyosis can be hereditary or acquired. Hereditary forms can present at birth or occur later in life. The approach to diagnostically focusing down toward a specific type of ichthyosis involves consideration of a number of factors including clinical dermatological features, age of onset, family history and pedigree and associated abnormalities (1). The clinical presentation is important. For example, the diagnoses most likely to be encountered when assessing a collodion newborn are different to those when assessing an adult with mild ichthyosis, atopic eczema and asthma. Some ichthyoses appear as primarily skin disorders (ichthyosis vulgaris, congenital autosomal recessive ichthyosis, epidermolytic hyperkeratosis, etc.). Others are characterized by involvement of additional specific organ systems which may be focused (e.g. Sjögren–Larsson syndrome with neurological involvement) or broad (e.g. trichothiodystrophy with a wide spectrum of multisystem involvement). Some are considered part of syndrome complexes (e.g. Keratitis-Ichthyosis-Deafness (KID) syndrome). While some ichthyoses can be diagnosed by skin biopsy (e.g. epidermolytic hyperkeratosis), for most ichthyosiform disorders, routine histology shows a variable pattern of hyperkeratosis with or without inflammation which is at best suggestive

but not diagnostic. Occasionally, the diagnosis of an ichthyosiform dermatosis may need to be distinguished from other disorders, such as the clinical presentation of a newborn with exfoliative erythroderma, where epidermolytic hyperkeratosis (bullous congenital ichthyosiform erythroderma) is clinically similar to staphylococcal scalded skin syndrome.

### 146.3 THE MORPHOLOGY OF NORMAL SKIN

The epidermis is a multilayered tissue which is firmly attached to the dermis by a series of interlocking structures, some of which are formed by the epidermal cells and others by the fibroblasts. The lowermost layer of cells is called the basal cell layer, which is the primary site of cell division. As these cuboidal cells move up they become more flattened in appearance and show increasing numbers of keratin intermediate filaments that traverse through the cells. The uppermost layer of living cells is the granular layer; this contains blue granules when histological sections are stained by hematoxylin and eosin. The cells die and cornify at the top of this layer to form the highly compact and flattened cells of the stratum corneum. The thickness of the epidermis and its various layers differ in various areas of the body, but is generally about 100 µm except for the palms and soles.

In most areas of normal skin, the epidermis is organized into units which consist of a single stack of stratum corneum cells surmounting a large number of less flattened, more undifferentiated viable cells. The cells of each stack interdigitate with neighboring cells to form a highly cohesive membrane. The epidermis renews itself about every month as a result of cell division in the basal layer, with a cell cycle time of several hundred hours.

**TABLE 146-1 Classification of Most Common Ichthyosiform Dermatoses**

	Mode of Inheritance	Age of Onset	Clinical Appearance	Associated Features	Histology
Ichthyosis vulgaris	Autosomal semi-dominant	Childhood	Fine, light scales; flexures spared; hyperlinear palms and soles; keratosis pilaris	Atopy	Decreased to absent granular layer
X-linked ichthyosis	X-linked recessive	Birth or infancy	Large, dark scales; lateral face and neck commonly involved; flexures variable involved; palms and soles normal	Corneal opacities (do not affect vision); steroid sulphatase deficiency	Normal granular layer
Congenital Autosomal Recessive Ichthyosis (lamellar ichthyosis and congenital ichthyosiform erythroderma)	Autosomal recessive rarely autosomal dominant	Birth	Lamellar Ichthyosis: large plate-like scales, severe ectropion, variable erythroderma. Congenital Ichthyosiform Erythroderma: fine white scales, pronounced erythroderma. Both forms have hyperkeratotic palms and soles, flexural involvement	Ectropion, eclabium; collodion presentation	Thickened granular layer
Epidermolytic hyperkeratosis	Autosomal dominant, high frequency new mutations	Birth	Blisters and erosions at birth and during childhood. Coarse, verrucous scales, particularly in flexures	Pungent odor; frequent skin infections	Vacuolar degeneration of suprabasilar epidermis

Some of the cells in the basal layer are stem cells and remain there.

Differentiation of epidermal cells is called keratinization or cornification and involves a number of metabolic pathways. The cells contain the usual complement of subcellular organelles essential for energy production, synthesis of proteins, etc. In addition, one finds tonofilaments, desmosomes, keratohyalin granules and cornified envelopes which are essential for full expression of epidermal differentiation.

Desmosomes are attachment units between cells which consist of a modified region of the cell membrane and an intercellular component. These must be broken down and remade as the cell moves through the different layers, but the mechanism for this has not been elucidated. The tonofilaments run from the attachment plaque of the desmosome to lamin which surrounds the nucleus. The basic subunit of the tonofilament is a double stranded protein with a unique X-ray diffraction pattern suggesting a supercoiled  $\alpha$ -helical configuration. These molecules aggregate side-to-side and end-to-end to give rise to keratin intermediate filaments. The filaments contain free sulfhydryl groups in the living layers but these become oxidized when the cell cornifies.

Keratohyalin granules consist of at least two components, one of which gives rise to the cornified cell envelope, the other acts as a matrix for the filaments. The matrix material is not essential for filament packing and may not be present in all epidermal cells, but the formation of a cornified envelope is a critical part of keratinization. Transglutaminase 1 is an enzyme that is important

in the formation of this insoluble envelope through calcium dependent cross-links between proteins, including loracrin and involucrin.

Lamellar granules appear in the cytoplasm of granular cells and their contents are extruded into the intercellular space. They are rich in lipid and protein and contribute to the barrier properties of the stratum corneum and possibly act as an additional intercellular glue for the cornified cells (2). As cells cornify at the base of the stratum corneum they die, and their subcellular organelles and most of their soluble proteins are broken down and reabsorbed. Most of their water is lost and the cells assume a flat and compact appearance. The desmosomes remain but are modified in appearance.

## 146.4 ICHTHYOSIS VULGARIS

### 146.4.1 Clinical Features

Ichthyosis vulgaris (MIM ID #146700) is the commonest form of the ichthyosiform dermatoses, comprising about 95% of all types, with at least 1% of the population involved to some degree.

The disease almost never starts at birth but appears sometime after the first 3 months of life. The scales are fine, white and adherent but may be coarser over the lower extremities (Figure 146-1). The turned-up margins of the scales give a rough feel to the skin and account for the 'pasted on' appearance. The extensor surfaces of the extremities are most severely involved, while the flexural and intertriginous areas are usually spared. The

**FIGURE 146-1** Ichthyosis vulgaris with fine, white, adherent scales.

**FIGURE 146-2** Ichthyosis vulgaris showing hyperlinear palms.

face and scalp may be involved but usually clear in later life. Unlike X-linked ichthyosis, scaling of the neck is uncommon, occurring in a reported 8.5% of patients with ichthyosis vulgaris. There is accentuation of the palmar and plantar markings (Figure 146-2). Follicular hyperkeratosis (keratosis pilaris), especially of the arms, thighs and buttocks, is a frequent feature. The nails and mucous membranes are free of lesions. The disorder is worse in cold, dry weather, when fissuring may occur, while in humid, warm weather there may be almost complete clearing.

Atopy is frequently associated with ichthyosis vulgaris and in some patients eczema is a major problem, often causing more symptoms than the hyperkeratosis itself. Eczema herpeticum may be a complication, and patients are more susceptible to fungal infections.

Histopathologically, skin of ichthyosis vulgaris shows decrease to absence of keratohyalin granules (Figure 146-3), and this can also be seen by electron microscopy (3). Profilaggrin is a polypeptide that contains a variable number of filaggrin repeats, the main protein of keratohyalin granules, and important in the formation of the epidermal barrier. Filaggrin binds to keratin intermediate filaments and is involved in their aggregation during the formation of the stratum corneum. The breakdown of filaggrin is

**FIGURE 146-3** Ichthyosis vulgaris histopathology. There is thickening of the stratum corneum and absence of granular layer.

thought to be involved in maintaining skin hydration and water retention within the stratum corneum (4).

Kinetic studies have shown normal values for epidermal cell transit time from basal layer to stratum corneum. This suggests that the excessively thick stratum corneum is due to retention of scale rather than to hyperproliferation. The barrier function of the epidermis is reduced in ichthyosis vulgaris which allows enhanced penetration into the skin (4-6).

#### 146.4.2 Genetics

The pattern of inheritance of ichthyosis vulgaris was originally thought to be autosomal dominant and the variation in the degree of involvement among family members was attributed to varying expression of the gene. It is now known that mutations in the gene encoding profilaggrin cause ichthyosis vulgaris and that the disease follows a semi-dominant inheritance pattern (3). The ichthyosis is mild in individuals who have one mutated allele, and more severe in the presence of two mutated alleles. Filaggrin abnormality is also a predisposing factor for atopic dermatitis (7). Two mutations (R501X and 2282del4) are common in the European population but others have been described (8). The filaggrin-null phenotype has been found in approximately one in 90 children in the north of England (9). Filaggrin mutations can be genetic modifying factors exacerbating other types of skin disorders, since filaggrin mutations are not uncommon. Individuals with other types of ichthyosis (e.g. X-linked ichthyosis) who also carry a filaggrin mutation can have a more severe phenotype (10).

#### 146.4.3 Management

There is no specific treatment for this lifelong disorder of cornification. The primary goal of therapy is removal of the excessively thick stratum corneum which lacks

sufficient moisture on its outer surface due to a lack of water binding compounds which are derived from filaggrin. However, one may achieve satisfactory improvement by hydrating and softening the skin surface with a lubricating cream. This can be particularly effective when a moisturizing cream is applied to wet skin after bathing or showering. Keratolytic agents which contain salicylic or lactic acid, ammonium lactate or urea are useful in removing scale (11,12), and often results in normal-appearing skin in a few days (13). Commercially available 12% ammonium lactate lotion by prescription is widely used and avoids the inconsistency of topically compounded preparations.

## 146.5 X-LINKED ICTHYOSIS

### 146.5.1 Clinical Features

Approximately one in every 6000 males is affected with X-linked ichthyosis (XLI, MIM ID #308100). In one large study (Wells and Kerr, 1966), the disease was present at birth in 17%, while 84% were affected by three months of age. The onset has not been reported to occur after one year of age.

Although some texts state that affected individuals may be born as collodion babies, most congenital presentations of XLI are milder. Subsequently, the skin develops a generalized involvement with the extensor surfaces most severely affected. The lateral face, neck and scalp may also be markedly involved, but the flexural and intertriginous surfaces are less so. The palms and soles are usually normal and keratosis pilaris ordinarily does not occur. The scales tend to be large, thick, adherent and dark (Figure 146-4), and have been described as having an unwashed appearance. This is a particular problem on the lateral sides of the neck.

Corneal opacities are frequently associated with this disorder (Sever et al., 1968; Jay et al., 1968; Costagliola et al., 1991), and female carriers may also show the opacities, which usually are not manifest before adolescence. The corneal opacities resemble gray-white filaments, commas or dots, and are located on the posterior capsule of Descemet's membrane. They are detected only by slit lamp examination and do not affect visual acuity. They are rarely seen in normal persons or other forms

of ichthyosis. Males with XLI may have cryptorchidism and cancer of the testes has been reported.

The histological pattern of the skin is that of orthokeratotic hyperkeratosis with a normal or thickened granular layer. There are no abnormalities of the adnexal structures, and follicular plugging is not present. Kinetic studies of epidermal cell renewal are normal, the same as ichthyosis vulgaris.

### 146.5.2 Genetics

The mode of inheritance of XLI is X-linked recessive. Thus, the disorder is usually evident only in males. Carrier females may show both minimal scaling of the legs, which resembles that of ichthyosis vulgaris, and corneal opacities. A deficiency of steroid sulfatase has been demonstrated in XLI, and this abnormality is specific and not observed in the other types of ichthyosis except multiple sulfatase deficiency. In most patients, the loss of steroid sulfatase results from deletion of a segment of DNA on the X chromosome, where the gene for the enzyme is located (14,15). Furthermore, it has been found to be genetically heterogeneous (Conary et al., 1987; Gillard et al., 1987). In addition, some families have been found which appear to have point mutations of the gene rather than deletion of a chromosome segment.

The locus for XLI has been assigned to Xp22.32. Patients have mutations or deletions of the steroid sulfatase gene (<http://www.ncbi.nlm.nih.gov/omim/300747>). Some patients have larger deletions which may include adjacent genes, and these continuous deletions syndromes may present with additional clinical features. These include the chondrodysplasia punctata gene (CDPX1; MIM #302950) (16), the gene for Kallman's Syndrome (KAL1; MIM ID +308,700) (17), the short stature gene (SHOX; MIM ID \*312,865) and a gene whose deletion is associated with mental retardation (18,19).

Placental steroid sulfatase deficiency and low serum and urine estriol levels had been found in pregnancies associated with difficulty in initiation of labor due to failure of cervical dilation. Subsequently this was recognized to occur in male fetuses that developed X-linked ichthyosis. Shapiro reported the association of X-linked ichthyosis with steroid sulfatase deficiency using cultured fibroblasts and labeled steroid substrates and later measured steroid sulfatase in 25 patients the enzyme deficiency. Patients with ichthyosis vulgaris and lamellar ichthyosis had normal values of the enzyme.

Although the sulfation of steroids may in part be a detoxification, it has been appreciated that some sulfated steroids may have a physiological role. Sulfated precursors appear to be important for testosterone production in the testes. Dihydroepiandrosterone sulfate (DHEAS) secreted by the adrenal gland and cholesterol sulfate by the liver are present in significant amounts in the blood, and these could be used as substrates in the production of other hormones or metabolic products. Placental

**FIGURE 146-4** X-linked ichthyosis with large, thick, dark scales.

steroid sulfatase appears to be important for the latter part of pregnancy. DHEAS secreted from either maternal or fetal adrenal glands must be desulfated prior to its aromatization in forming estrogen, and this occurs primarily in the placenta.

Several disorders of lipid metabolism have been shown to be associated with ichthyosis-like changes of the skin. In hypothyroidism one observes such alterations in the skin, and ingestion of pharmacological doses of nicotinic acid and triparanol, which decrease blood cholesterol, cause similar changes. In Refsum disease (MIM #266500), where there is an accumulation of phytanic acid in the body due to a deficient alpha-oxidation, ichthyosis is one of the multisystem abnormalities which are observed. Finally, in multiple sulfatase deficiency (MIM #272200), where arylsulfatases A, B and C are all reduced, and which is caused by a mutation in a sulfatase-modifying factor-1 gene, (20,21) ichthyosis is a constant feature (22).

Steroid sulfatase is present in the lamellar bodies, which transport and secrete it into the intercellular spaces where it provides cholesterol for barrier function (22,23). In the normal epidermis, cholesterol sulfate decreases at the epidermal surface facilitating desquamation of the terminally differentiated corneocytes. As a result of steroid sulfatase deficiency, cholesterol sulfate accumulates in the epidermis leading to failure of normal corneocyte desquamation and a retention hyperkeratosis. A recent study has investigated the role of steroid sulfate as a protease inhibitor. It has been previously reported that desmosomes play a key role in the adhesion of corneocytes, and their digestion by two types of serine proteases leads to desquamation. A build-up of steroid sulfate, a protease inhibitor would thus retard desquamation in X-linked ichthyosis (24). Elias (23) confirmed this inhibition and further showed that there is a non-lamellar phase separation in the interstices of the stratum corneum, Nemes showed that cholesterol sulfate altered the function of transglutaminase 1 (25). Cholesterol sulfate has also been found to be a transcriptional regulator of transglutaminase 1 and involucrin expression.

It has been reported that the diagnosis of X-linked ichthyosis can be established by a determination of steroid sulfatase in specimens of callus and scale (26). Steroid sulfatase has also been studied in peripheral blood leucocytes with similar results, and affected individuals show more rapid mobility by electrophoresis of lipoproteins (27). Biochemical diagnosis of X-linked ichthyosis consists of demonstrating steroid sulfatase deficiency by lack of enzymatic activity (direct biochemical assays) or by showing an increase in substrates. Direct biochemical techniques work by demonstrating either steroid sulfatase or arylsulfatase C deficiency in tissues where they are usually found, which includes placenta, skin, fibroblasts, leukocytes and keratinocytes. Fluorescent in situ hybridization is commonly used for diagnosis as biochemical testing is not widely available.

### 146.5.3 Management

The treatment of X-linked ichthyosis is similar to that described for ichthyosis vulgaris. It is exacerbated by dry climate and improved by humid weather. Topical lubrication and keratolytics such as urea and lactic acid usually provide substantial relief.

## 146.6 AUTOSOMAL RECESSIVE CONGENITAL ICHTHYOSIS

### 146.6.1 Clinical

Autosomal recessive congenital ichthyosis (ARCI) is a heterogeneous group of disorders which present at birth and share autosomal recessive inheritance. The typical presentation is that of a baby born enveloped within a casing of thick stratum corneum resembling collodion, hence the name collodion baby. Other newborns may have generalized erythroderma. The incidence is about one per 300,000 live births. Tension from the collodion membrane may result in pulling out of the eyelids (ectropion) and lips (eclabium) (Figure 146-5). Constriction from the membrane may restrict breathing or compromise blood flow to the limbs or digits. Over days, the membrane begins to fissure and peel, leaving an erythematous skin. Complete desquamation may take several weeks. During the neonatal period, imperfect barrier characteristics of the stratum corneum and breaks in the skin lead to an increased susceptibility to bacterial infection. Therefore, these infants should be monitored for infection. Hydration and lubrication can facilitate desquamation. In cases where the membrane is causing constriction of limbs or breathing, systemic retinoids have been used to facilitate desquamation.

Over time, the skin may develop into different clinical phenotypes, with the most common being lamellar ichthyosis (LI, MIM ID #242300) and congenital ichthyosiform erythroderma (CIE, MIM ID #242100). In older literature, before LI and CIE were recognized as different entities based on clinical features, both were lumped under the name non-bullous congenital ichthyosiform erythroderma (NBCIE). CIE is characterized by skin with fine white scale and erythroderma, which may

**FIGURE 146-5** Autosomal recessive congenital ichthyosis with collodion presentation. Newborn with ectropion, eclabium and collodion membrane which is cracking.

**FIGURE 146-6** Congenital autosomal recessive ichthyosis-lamellar ichthyosis. Large, thick scales over the skin of the face with ectropion. (A) Showing large sheets of scale on legs. (B) Verrucous hyperkeratosis on flexural surfaces of the arm and trunk.

improve at the time of puberty. In contrast, the skin of LI is brown in color with thick, large, plate-like scale.

In LI, the erythematous, thick skin of the newborn becomes less red over time and the skin becomes covered with large, thick scales, which may form a mosaic pattern (Figure 146-6). The scale often tends to be most severe over the lower extremities. The palms and soles are usually hyperkeratotic and show increased markings. Fissuring of the hands and feet is a common problem. Hair is present but the scalp is often covered with adherent scale, and bacterial infection may occur and in conjunction with traction from the tight skin, may result in scarring alopecia. Ridges and grooves form in the nails. Ectropion is usually present, particularly in dry weather, and may be severe in later life. Decreased sweating is common and associated heat intolerance may be severe during exercise or in hot weather.

In CIE, the erythema present during the newborn period persists as generalized erythroderma and the skin is covered with fine, white scale (Figure 146-7). There may be varying severities of ectropion, eclabion, hypohidrosis with heat intolerance and alopecia.

Histological examination in LI shows hyperkeratosis, a thickening of the stratum corneum. In CIE, there is usually parakeratosis, a retention of the nuclei in the stratum corneum. This may reflect the finding that the rates of epidermal proliferation in the skin of CIE are much higher compared to LI (28).

While many patients can be clinically classified as LI or CIE, others have clinical features intermediate between these two presentations. These intermediate phenotypes have made a genotype/phenotype correlation difficult to define.

### 146.6.2 Genetics

Linkage analysis done in a number of families with the severe phenotype of classic LI (large plate-like scale,

**FIGURE 146-7** Congenital autosomal recessive ichthyosis – congenital ichthyosiform erythroderma. There is generalized redness and fine, white scales. In contrast to severe LI, this patient has minimal ectropion.

ectropion, and eclabion) mapped the diseased gene to chromosome 14q11 near the transglutaminase 1 gene (*TGM1*; 190,195) (29). Subsequently, in some families the disease was shown to result from mutations in the gene encoding transglutaminase 1 (30,31). This is an enzyme that is important in cross-linking proteins during the formation of the fully differentiated keratinocyte, the corneocyte. Loricin and involucrin are major precursor proteins to the cornified cell envelope expressed late in epidermal differentiation. Involucrin expression starts in the upper spinous layer and precedes loricin expression, which is restricted to the granular layer. Both proteins become cross-linked by the activity of transglutaminases as major components of the cornified cell envelope by  $\epsilon$ -( $\gamma$ -glutamyl) lysine bonds.

The molecular heterogeneity of ARCI has been confirmed with the finding of mutations in a variety of genes whose function relates to epidermal differentiation. In the United States, about half of patients with ARCI were found to have germline mutations in *TGM1* (32). In other families, mutations have been found in *ALOX12B*, (603,741), *ALOXE3* (607,206) (lipoxygenases), *ABCA12*, (MIM ID \*607,800, ATP-binding cassette transporter), *ichthyin* (MIM ID \*609,383, divalent cation transporter), and *CYP4F22* (MIM ID \*611,495, cytochrome P450 family) (33). Mutation types include missense, nonsense, deletion, splice-site, and insertion (34). While a definitive genotype/phenotype correlation has been elusive, *TGM1* mutations in ARCI has been associated with collodion presentation at birth, ectropion, plate-like scale and alopecia (32).

The usual pattern of inheritance is autosomal recessive, but an autosomal dominant type has been reported (35).

### 146.6.3 Management

Treatments are based on managing symptoms, which can include thickening of the skin with cracking and fissuring. Decreased sweating may cause heat intolerance. While the abnormal skin may be thick, the skin barrier function is abnormal leading to increased transepidermal water loss and there may be enhanced penetration of drugs. In addition to removing thick scale (keratolysis), hydration and lubrication are the main goals of treatment. Soaking softens the thick stratum corneum which can then be more easily removed with textured sponges or abrasives. Lubricating bath oils and topical lubricants help seal in the moisture. Topical keratolytics such as urea and lactic acid help thin hyperkeratotic areas. Topical salicylic acid is also used but caution is necessary because with an abnormal barrier there may be enhanced absorption and risk of toxicity. The oral retinoids, isotretinoin and acitretin, can produce a marked improvement (36–38). Gene replacement with retroviral vectors bearing the transglutaminase 1 gene has been successful in restoring function of keratinocytes cultured from patients with lamellar ichthyosis, but clinical utility has not been established (39).

## 146.7 EPIDERMOLYTIC HYPERKERATOSIS

### 146.7.1 Clinical Features

Epidermolytic hyperkeratosis (EHK, MIM ID #113800) was previously called bullous congenital ichthyosiform erythroderma. It occurs in one per 200,000–300,000 live births and usually presents at birth (Figure 146-8) with generalized erythema and blistering. This may result in extensively denuded areas. These moist, raw surfaces may lead to secondary infections and sepsis. The

diagnosis may be confused with other blistering diseases, such as epidermolysis bullosa or staphylococcal scalded skin syndrome. The erythema gradually subsides a few months after birth, and the bullae appear less frequently.

The clinical appearance of the skin varies between families, and six clinical phenotypes have been described (40). In some patients with generalized involvement, after the newborn period the disease may evolve into thick brown verrucous scale which often has a cobblestoned appearance accentuated at the flexures and over the knees and elbows (Figure 146-9). In others there may be generalized erythroderma with scaling. Some individuals have limited involvement with primarily palmar plantar hyperkeratosis and scaling limited to flexural areas. The skin in EHK may have a strong odor, thought to be due to bacterial overgrowth.

The histological picture of EHK is distinctive with hyperkeratosis, papillomatosis and acanthosis (41). There is a vacuolar degeneration of the epidermis above the basal layer which leads to blistering. Large clumped keratohyalin granules are present in a thickened granular layer. There is hyperproliferation of the keratinocytes within the epidermis as in lamellar ichthyosis, but in spite of its thickness, the epidermal barrier is defective,

**FIGURE 146-8** Epidermolytic hyperkeratosis. A newborn with peeling of the epidermis leaving erosions. (Courtesy of Dr. Joseph McGuire.)

**FIGURE 146-9** Epidermolytic hyperkeratosis. Thick verrucous hyperkeratosis and scaling over the knees and legs with erosions where hyperkeratosis has blistered off.

resulting in increased water loss through the abnormal stratum corneum (Figure 146-10). Ultrastructural studies demonstrate clumping of keratin intermediate filaments beginning in the first suprabasilar layer. These clumps contain keratin 1 and 10 (42). This and the histopathology of vacuolar degeneration of the suprabasilar epidermis are the result of destabilization of the cytoskeleton of differentiated keratinocytes. Keratins 1 and 10 pair as heterodimers to form the keratinocyte intermediate filaments which make up the cytoskeleton of suprabasilar keratinocytes. The cytoskeleton of the epidermal cells in the basal layer is composed of keratins 5 and 14. In EHK the cytoskeleton of the suprabasilar keratinocytes is fragile and prone to disruption. Mutations in the genes *KRT1* (MIM ID \*139,350) or *KRT10* (MIM ID \*148,080) coding for either keratin 1 or 10, respectively, have been found in families with EHK (42,43). These mutations occur in regions of the keratin molecule which are important for filament assembly. A genotype/phenotype correlation has been identified in that most families with mutations in *KRT1* have involvement of the palms and soles, whereas those with mutations in *KRT10* tend to have absence of severe palm and sole hyperkeratosis (40).

Several disorders resembling EHK have been described. Ichthyosis bullosa of Siemens (MIM ID #146800) is a rare autosomal dominant skin disorder with clinical features similar to EHK, but which occur in the more superficial layers of the epidermis. It is characterized by a mild epidermolytic ichthyosis which tends to localize to the flexures. Affected individuals are born with extensive superficial blistering, which develops into hyperkeratotic plaques over the extremities (44). However, the hyperkeratosis and blistering is milder than in EHK. Histological exam shows that lysis of keratinocytes is restricted to the upper spinous and granular layer. This results in peeling that occurs superficially, and leaves an area under the peeled layer that is dry and this has been called molting (Figure 146-11). The term epidermolytic ichthyosis has been suggested for this group of disorders (45).

### 146.7.2 Genetics

EHK is inherited as an autosomal dominant trait and due to mutations in the genes encoding keratin 1 or 10. But there is a high frequency of spontaneous mutation, so many cases have no family history (46). Prenatal diagnosis, previously accomplished by histology of fetal skin biopsy, is now done by direct gene sequencing (47).

In ichthyosis bullosa of Siemens, mutations are found in (*KRT2E*; 600,194), the gene encoding keratin-2, a keratin that is expressed only in the more superficial layers of the epidermis. A form of EHK confined to only the palms and soles was described by Vöerner. This disorder is associated with mutation in (*KRT9*; 607,606) which encodes keratin 9, a protein that is expressed only in the palms and soles. Ichthyosis hystrix of Curth

**FIGURE 146-10** Epidermolytic hyperkeratosis. Histopathology showing balloon degeneration of the epidermis above the basal layer.

**FIGURE 146-11** Ichthyosis bullosa of Siemens. Peeling of the superficial epidermis leaving a dry base, which has been called molting.

and Maklin (IHCM) has variable expression from limited to volar skin to generalized involvement and clinically resembles EHK, but blistering does not occur. In one family with IHCM a mutation in the variable tail region of the keratin 1 gene (MIM ID \*139,350) was found which leads to a retraction of the cytoskeleton from the nucleus and failed translocation of loricrin to desmosomal plaques (48).

### 146.7.3 Management

The skin of EHK has thickened areas of hyperkeratosis but also has a propensity toward blistering. Treatment includes hydration, lubrication and keratolytics, and

varies with the clinical presentation. The skin of EHK is often covered with thick hyperkeratotic horn, which may be subject to traction that may lead to blistering. For individuals with thick, hyperkeratotic skin, keratolytics to remove the thick horn can help prevent blistering. Oral retinoids may be very helpful to minimize the thick scale. Because they may enhance blistering, particularly at higher doses, therapy with systemic retinoids should be started at a low dose. Systemic and topical antibiotics are used when infection is present. Sodium bicarbonate or bleach baths may help to control the odor.

## 146.8 ICHTHYOSIS OF THE NEWBORN

Ichthyosis of the newborn describes a group of disorders present at birth or shortly after that may have different genetic defects. The diagnosis may be established by the appearance of the infant, the course of the disorder and biopsy of the skin.

### 146.8.1 Collodion Baby

**146.8.1.1 Clinical Features.** The most common of these disorders is the collodion baby; in which the infant is enclosed in a parchment-like membrane at birth. The tightly fitting brownish membrane (see [Figure 146-5](#)) distorts the features of the infant. The membrane dries rapidly and begins to fissure and split. The babies may have difficulty in nursing and breathing and exhibit problems in thermoregulation and are at risk of infection. The skin of these babies may evolve over time into one of the characteristic ichthyosis phenotypes, such as lamellar ichthyosis or congenital ichthyosiform erythroderma, or to a less specific intermediate phenotype (see [Table 146-2](#)). Alternatively, the skin may improve during infancy as occurs in the self-healing collodion baby ([49,50](#)), in which affected children clear shortly after birth or have very mild scaling of the skin for some months (Van Gysel et al., 2002). This has been reported in siblings with unaffected parents and is likely to be inherited as an autosomal recessive trait. The genetic basis of self-healing collodion baby has been reported to include mutations in *ALOX12B*, *ALOXE3* and *TGM1* ([51–53](#)). Patients with trichothiodystrophy may present at birth with taut, shiny membrane, or with just erythroderma.

Congenital ichthyosis may present with redness and scaling at birth rather than as a collodion baby and can be confused with the congenital ichthyoses associated with involvement of other organs, and this should make the physician search more carefully for other abnormalities. These may not be apparent immediately but may take some months to appear, as, for instance, in the Sjögren-Larsson syndrome.

Collodion presentation has also been reported in trichothiodystrophy, ankyloblepharon-ectodermal defects-cleft lip/palate (AEC) syndrome, chondrodysplasia punctata,

Gaucher disease, loricrin keratoderma, neutral lipid storage disease and X-linked hypohydrotic ectodermal dysplasia ([54](#)). Although some texts state that X-linked ichthyosis and epidermolytic hyperkeratosis may start as a collodion baby (Beare and Rook, 1972), this is likely not to be the case. The latter may present with blistering at birth or shortly after, and the peeling epidermis is confused with a collodion membrane.

**146.8.1.2 Management.** The collodion babies are best managed by placing them in a high-humidity, temperature-controlled incubator and carefully monitoring their vital signs. The membrane has a composition similar to stratum corneum and is pliable when kept moist. Topical petrolatum based creams and emollients (preferable sterile) are often used to keep the skin hydrated and soft but it has been suggested that they may contribute to infection ([55](#)). Hand washing and measures to limit exposure to infection should be implemented. The membrane should not be mechanically removed since this may tear off the epidermis, causing an increased risk of infection and resulting in scarring. However, the membrane sometimes restricts respiration or can cause constriction of extremities or digits. Constrictions can be released with mechanical means ([56,57](#)) and rarely systemic retinoids are used. Clear fluids should be given for the first few days until it is determined that the child can swallow properly and is not aspirating. Evidence for infection should be looked for and, if present, treated promptly and aggressively.

### 146.8.2 Harlequin Ichthyosis

**146.8.2.1 Clinical Features.** The harlequin ichthyosis is a distinct genetic entity in which the newborn has such a strikingly grotesque appearance that it is usually not confused with the other types of ichthyosis ([Figure 146-12](#)). It is considered the most severe presentation of congenital ichthyosis. The skin has a thick armour-like covering with an off-white color which has deep fissures running in different directions. There is marked ectropion, the palpebral conjunctiva obscuring the globe, which is normal. There is a degree of eclabium which gives a fish-mouth appearance. The external ears are poorly developed or absent. The hands and feet have a grayish white color and the fingers and toes may look necrotic, perhaps from interruption of the blood supply by constriction. Clinical evaluation and post-mortem examination have not revealed a consistent abnormality of other organ systems.

In the past this was called harlequin fetus, because most were born premature and succumbed shortly after birth, but with enhanced management individuals can survive, hence the term harlequin baby. Subsequently the skin evolves into an ichthyosiform erythroderma with redness and fine scaling ([58](#)).

**146.8.2.2 Genetics.** Previously there was some confusion about classification of the harlequin fetus, with some

**TABLE 146-2 Autosomal Recessive Congenital Ichthyosis: Collodion and Harlequin Presentations in the Newborn**

	Disease		Characteristic Clinical Features	Mutated Gene	Protein
HARLEQUIN	HARLEQUIN	MOST SEVERE	Premature birth, severe ectropion/eclabium, thick armor-like skin with deep fissures.	ABCA12	ATP-binding cassette subfamily A member 12
COLLOIDON	LAMELLAR ICHTHYOSIS (LI)		Ectropion/eclabium at birth. After shedding of collodion membrane skin develops large, brown, plate-like scale.	TGM1 in most; ABCA12 in some	Transglutaminase 1
	INTERMEDIATE PHENOTYPES BETWEEN LI AND CIE *		Variable congenital presentation (collodion or only erythroderma) and subsequent skin manifestations	CYP4F22	Cytochrome P450 family 4 subfamily F, polypeptide 22
	CONGENITAL ICHTHYOSIFORM ERYTHRODERMA (CIE)*		After shedding of collodion membrane skin appears red (erythroderma) with fine, white scale.	ALOXE3 & ALOX12B in some NIPAL4 (ICHTYN) reported TGM1 reported	Arachidonate lipoxygenase 3 & arachidonate 12-lipoxygenase; Ichthyin Transglutaminase 1
	SELF HEALING COLLODION BABY	MILDEST	Erythroderma or collodion membrane at birth. Clears, often within weeks leaving minimal redness and scaling	ALOXE3; ALOX12B I TGM1	Arachidonate lipoxygenase 3 & arachidonate 12-lipoxygenase; Transglutaminase 1

\*Genotype/phenotype correlation poorly defined.

**FIGURE 146-12** Harlequin fetus. Infants are usually born premature, with marked ectropion and eclabium, and skin broken into large plaques separated by deep fissures.

reports suggesting that the disorder may consist of phenotypically similar but genetically distinct entities. Dale and Karn (1993) and colleagues had classified harlequin fetus ichthyosis based on the electron microscopic appearance of keratohyaline granules, keratin expression, presence or absence of profilaggrin/filaggrin and possible defective protein phosphatase 2A expression. All individuals had abnormal lamellar granules and absent lipid lamellae. Harlequin fetus is an autosomal recessive trait. There is now strong evidence that mutations in the *ABCA12* gene (MIM ID \*607,800), which codes for a protein involved in lamellar granule secretion and lipid transport, are the genetic basis of the disorder (59,60). Most mutations in harlequin ichthyosis are truncation mutations which lead to loss of function of the *ABCA12* peptide. Mutations in the same gene in other families have been associated with the other clinical phenotypes of ARCI, including lamellar ichthyosis and congenital ichthyosiform erythroderma (61).

Previously, prenatal diagnosis had been accomplished by biopsy of fetal skin and possibly by sonographic features (62). Characteristic morphological abnormalities of harlequin ichthyosis can be detected as early as 17 weeks gestation. Clumps of abnormally keratinized cells with an increased amount of large lipid deposits were detected in amniotic fluid cell pellets indicating that the fetus was affected with harlequin ichthyosis. These results were confirmed by fetal skin biopsy, which was consistent with harlequin ichthyosis at 21 weeks gestation (63). Prenatal

diagnosis and carrier detection is currently available by molecular methods.

**146.8.2.3 Management.** There are several reports of successful treatment with intensive management in the neonatal period in conjunction with systemic retinoid treatment, such as etretinate or acitretin (64–66). After the newborn period, the skin develops the appearance of congenital ichthyosiform erythroderma (64).

## 146.9 HYPERKERATOSIS OF THE PALMS AND SOLES

Hyperkeratosis of the palms and soles accompanies many of the diseases in this chapter, and those in which hyperkeratosis of the palms and soles is a major clinical manifestation or are well known palmar plantar keratoderms (PPK) are listed in Table 146-3 (for a general review, see Ratnaveil and Griffiths, 1997 (67)).

These hereditary PPKs are a group of genodermatoses characterized by abnormal thickening of the epidermis of the palms and soles. They are distinguished from each other by severity (mutilating vs. non-mutilating), distribution (punctate vs. focal vs. diffuse), involvement of other areas of the skin, associated abnormalities, histopathology (epidermolytic vs. nonepidermolytic) and inheritance. Three different clinical phenotypes of autosomal dominant PPK are shown. The Unna Thost type of PPK has diffuse involvement (Figure 146-13). In contrast, punctuate keratoderma (Figure 146-14) has small discrete areas of thickening. In the striate form of PPK (Figure 146-15) hyperkeratosis is arrayed in linear bands.

The keratins are the more common genes mutated in the PPKs. Keratins are expressed as a pair of acidic and basic proteins which map to a cluster on chromosome 17q and 12q respectively, with 5/14 and 1/10 the major pairs of the basal and super basal layers. Since obligate heterodimers make up the keratin filaments, a mutation in either the acidic or basic type of keratin protein of a pair may cause disease. In addition to the main expression pairs, there are a number of accessory keratins expressed in particular epithelial tissues. Keratin 9 is specifically expressed in the suprabasal cells of the palms and soles. Keratin 2e is localized in the more differentiated epidermal cells. Keratins 16/6a and 17/16b are expressed in the upper outer hair root sheath, nail bed and palm and sole epidermis. Striate PPK has been associated with mutations in desmosomal proteins including desmoglein 1 (DSG1 gene 125,670, 18q11–12) and desmoplakin as well as keratins 1 and 16. Naxos disease (MIM ID #601214), caused by mutations in the plakoglobin gene (JUP; 173,325, 17q21), is a striate PPK with woolly hair and cardiac abnormalities with a risk of sudden death. Carvajal syndrome (MIM ID #605676), with striate PPK, woolly hair and left ventricular cardiomyopathy is caused by mutations in the gene encoding desmoplakin (DSP; 125,647, 6p24).

**TABLE 146-3    Palmar Plantar Keratodermas (PPK)**

Disease	Inheritance	Onset	Appearance	Associated Features	Mutated Gene [Locus]	Abnormal Protein	Abnormal Function
Cardiofaciocutaneous syndrome	Autosomal dominant or sporadic	First year	Thick, yellow plaques on palms, soles, and extensor surfaces	Sparse hair, mental retardation; cardiac abnormalities; distinctive facies; growth failure	KRAS [12p12.1] BRAF [7q34] MEK1 [15q21] MEK2 [19q13.3]	KRAS BRAFMEK1 MEK2	Proteins that interact commonly with ERK participate in regulating different proliferative and apoptotic pathways
Carvajal syndrome	Autosomal recessive	1st year	Epidermolytic PPK	Woolly hair, electrocardiogram abnormalities; dilated cardiomyopathy	DSP [6p24]	Desmoplakin	Adhesion protein
Erythrokeratoderma variabilis (EKV)	Autosomal dominant	Infancy	In addition to PPK, generalized or localized hyperkeratosis and migratory red patches.		GJB3 [1p35.1] GJB4 [1p35.1]	Connexin 31 Connexin 30.3	Gap junction protein Gap junction protein
Focal PPK with oral mucosa hyperkeratosis	Autosomal dominant	First decade	Calluses develop primarily over plantar pressure points	Oral leukokeratosis; nail changes; epidermolysis is a variable histologic feature	KRT16 [17q]	Keratin 16	Keratinocyte cytoskeleton
Howel-Evans Syndrome	Autosomal dominant	Age 5–15 years	Diffuse, symmetric, non-transgradient keratoderma, involving primarily plantar pressure points	Esophageal carcinoma; oral leukokeratosis; normal nails	[17q25]		
KLICK (keratosis linearis with ichthyosis congenita and sclerosing keratoderma) syndrome	Autosomal recessive	Birth	Diffuse keratoderma with sclerosis, deformities, pseudoainhum	Multiple keratotic papules, in symmetrical cordlike array over flexures	POMP [13q12.3]	Proteosome maturation protein	Protein degradation

Mal de Meleda	Autosomal recessive	Infancy	Diffuse, transgradiens PPK with painful fissures and malodor; hyperkeratotic plaques over elbows & knees	Koilonychia and subungual hyperkeratosis; leukokeratosis; hyperhidrosis	SLURP1 [8qter]	Secreted Ly6/plaur domain-containing protein 1	Suggested as a secreted protein
Naxos disease	Autosomal recessive	Infancy	Striate PPK	Arrhythmogenic right ventricular dysplasia/cardio-myopathy, woolly hair; risk of sudden death	JUP [17q21]	Plakoglobin	Cytoplasmic protein associated with desmosomes; intermediate junctions
Pachyonychia congenita (Type 1, PC1)- Jadassohn-Ledwadowsky type	Autosomal dominant	Infancy	Painful focal hyperkeratotic calluses	Pincer or other nail dystrophy, oral leukokeratosis; follicular hyperkeratosis	KRT16 [17q12–q21] or KRT6A [12q13], but may be KRT17 or KRT6B	Keratin 16 or 6a, but may be keratin 17 or 6b	Keratinocyte cytoskeleton
Pachyonychia congenita (Type 2, PC2)- Jackson-Lawler type	Autosomal dominant	Infancy	Painful focal hyperkeratotic calluses	Pincer or other nail dystrophy, multiple steatocystomas; minimal oral involvement; natal teeth; pili torti	KRT17 [17q12] or KRT6B [12q3], but may be KRT16 or KRT6a	Keratin 17 or 6b, but may be keratin 16 or 6a	Keratinocyte cytoskeleton
Papillon-Lefèvre syndrome	Autosomal recessive	Infancy to 5 years	Diffuse, transgradiens PPK with spread to Achilles tendon areas, elbows & knees	Severe periodontitis; dural calcification; deafness; pyogenic infections	CTSC (DPPI) [11q14.1–q14.3]	Cathepsin C	Lysosomal protease
Punctate PPK	Autosomal dominant	2nd or 3rd decade	Multiple punctate keratoses over entire palmoplantar surfaces	Punctate keratoses induced by trauma; variable nail changes	[15q22–q24]		
Striate PPK Type 1	Autosomal dominant	Infancy	Linear hyperkeratotic plaques along plantar aspect of fingers. May have more diffuse involvement of soles.		DSG1 [18q12.1–q12.2]	Type 1: Desmoglein 1	Adhesion protein

TABLE 146-3 Palmar Plantar Keratodermas (PPK)—cont'd							
Disease	Inheritance	Onset	Appearance	Associated Features	Mutated Gene [Locus]	Abnormal Protein	Abnormal Function
Striate PPK Type 2	Autosomal dominant	Infancy	Linear hyperkeratotic plaques along plantar aspect of fingers. May have more diffuse involvement of soles		DSP [6p24]	Type 2: Desmoplakin	Adhesion protein
Striate PPK Type 3	Autosomal dominant	Early childhood	Linear hyperkeratotic plaques along plantar aspect of fingers. May have more diffuse involvement of soles		KRT1 [12q13]	Type 3: Keratin 1	Keratinocyte skeleton
Unna-Thost Type	Autosomal dominant	1st 2 years	Diffuse, waxy PPK	Parrot-beaking of fingernails; secondary dermatophyte infection; nonepidermolytic histopathology	KRT1 [12q13]	Keratin 1	Adhesion protein
Vohwinkel syndrome (keratoderma hereditaria mutilans; mutilating keratoderma with ichthyosis)	Autosomal dominant	Infancy	Diffuse, honeycombed PPK	Pseudo-ainhum; starfish shaped keratoses on extensor surfaces of elbows, knees and knuckles	LOR [1q21]	Loricrin	Cornified form
With hearing loss					GJB2 [13q11–q12]	Connexin 26	Gap junction
Vörner Type	Autosomal dominant	Infancy	Diffuse, 'dirty' PPK	Clinically similar to Unna-Thost; epidermolytic histopathology	KRT9 [17q12–q21]	Keratin 9	Keratinocyte skeleton; refined to plantar

Striate PPK Type 2.

**FIGURE 146-14** Hereditary PPK. Punctate type of PPK.

**FIGURE 146-15** Striate PPK. Linear bands of hyperkeratosis along length of fingers.

In addition to the diseases listed in the [Table 146-3](#), there are a large number of disorders referenced in OMIM in which there is some form of keratoderma, but the major feature in most is involvement of some other tissue or organ. Some are quite common disorders such as the ichthyoses, while many others are not. The titles are clues to their other manifestations, but not completely so.

The current management of the palmoplantar keratodermas involves the regular use of topical keratolytics and manual paring of the hyperkeratoses. Oral retinoids may be helpful in some patients. Associated dermatophyte infections are common and can be treated with topical or oral antifungal agents.

### 146.9.1 Pachyonychia Congenita

Pachyonychia congenita is an autosomal dominant keratoderma characterized by painful hyperkeratotic callosities and plaques of the plantar surfaces of the feet, hypertrophic nail dystrophy, follicular hyperkeratosis, oral leukokeratosis and cutaneous cysts. Cutaneous features are highly variable. Nail changes start in infancy with an upward growth of the nail plate with prominent subungual hyperkeratosis. Palmar callosities may occur with physical labor. Plantar callosities, which may begin in childhood, are painful, may be accompanied by blistering and hyperhidrosis and are usually the most disabling aspect.

Two types have been described (see [Tables 146-2](#)). Type I (Jadassohn–Lewandowsky type, MIM ID #167200) includes oral white plaques (non-premalignant leukokeratosis) and hyperhidrosis of the hands and feet. Follicular hyperkeratoses may occur. The oral leukokeratosis may be the earliest sign, and laryngeal involvement, manifested by hoarseness, has been described. Type II (Jackson–Lawlor type, MIM ID #167210) may include natal teeth, steatocystomas and pili torti.

**146.9.1.1 Genetics.** PC is caused by mutations in one of four keratin genes. Keratins encode the cytoskeleton of epithelial cells. Previously, mutations in *KRT6A* (MIM ID \*148,041) or its expression partner *KRT16* (MIM ID \*148,067) have been found in type 1 and mutations in *KRT6B* (MIM ID \*148,042) or *KRT17* (MIM ID \*148,069) in type 2. These mutations result in an abnormal keratinocyte cytoskeleton, which leads to cell fragility. Data from the International PC Research Registry ([www.pachyonychia.org](http://www.pachyonychia.org)) shows phenotypic overlap between these types and a new classification is being developed to link the mutation and clinical phenotype (68).

### 146.9.2 Trichothiodystrophy

Trichothiodystrophy (MIM ID #601675) is an autosomal recessive disorder characterized by sulfur deficient, brittle hair and a broad spectrum of clinical manifestations. Newborns usually present with erythroderma or a collodion-like membrane, and may have low birth weight and congenital cataracts. An extensive review of the literature has identified a wide spectrum of clinical features, including abnormalities at birth, pregnancy complications in mothers carrying an affected fetus, a high frequency of recurrent infections, and a high mortality in children (69). The pregnancies of mothers carrying

affected fetuses may be complicated by abnormalities such as preterm labor or pre-eclampsia (70). Clinical features include photosensitivity, intellectual impairment, short stature, microcephaly, recurrent infections, bone abnormalities of osteosclerosis and osteopenia, ichthyosis and nail dystrophy. Magnetic resonance imaging of the brain usually shows dysmyelination. Children typically have a very pleasant, outgoing personality and most have some degree of growth failure.

The term trichothiodystrophy (TTD) was proposed by Price in 1980, who recognized the fact that despite the broad spectrum of clinical abnormalities, all patients have sulfur deficient, brittle hair. When examined under light microscopy, the short, brittle, broken hairs of the patients appear to have hair shaft abnormalities of trichoschisis (a sharp transverse break), ribboning, and trichorrhexis nodosum-like defects (71,72). Under polarizing microscopy the hair shafts exhibit a distinctive pattern called tiger-tailed banding (Figure 146-16) which is diagnostic. Once the diagnosis is suspected, examination of hair shafts provides a quick and easy diagnostic test. The hair shafts are prone to breakage because of a reduction in high sulfur matrix proteins. Amino acid analysis of hair shafts shows reduced levels of cysteine and cystine.

TTD encompasses patients who have been described as having Tay syndrome, Amish brittle hair syndrome, Sabinas brittle hair syndrome and Pollitt syndrome. About half of the patients with TTD may have clinical photosensitivity, which can range from mild to severe. Patients with TTD may have mutations in the same DNA repair genes that cause xeroderma pigmentosum, which is associated with a large increase in the risk for development of skin cancer. In contrast, TTD is not associated with an increase in skin cancer risk.

**146.9.2.1 Genetics.** TTD is inherited in an autosomal recessive pattern and can be caused by mutations in genes involved in nucleotide excision repair including XPD (*ERCC2*, MIM ID \*126,340), XPB (*ERCC3*, MIM ID \*133,510) or TTDA (*TFB5*, MIM ID \*608,780). Most patients have mutations in the *XPD* gene. The proteins

made by these genes are components of the transcription factor TFIIH (*TFIIH*, MIM ID \*189,972) that is involved in both DNA repair and transcription. Some patients have mutations in *TTDN1* (MIM ID \*609,188), a gene whose function is not known. The clinical manifestation of TTD and xeroderma pigmentosum are very different, but may be caused by different mutations in the same genes. TFIIH is a helicase involved in both DNA repair and transcription. It is thought that mutations causing xeroderma pigmentosum affect the repair function while those causing TTD affect the transcription related function (73).

**146.9.2.2 Management.** Monitoring for infection, developmental delay, cataracts, bone abnormalities and growth difficulties, and providing appropriate support for learning, adequate nutrition, and ambulation are important. Awareness of the possibility of photosensitivity and if present, provision of protective measures with sunscreen and protective clothing is necessary. In addition to sun exposure, some photosensitive patients may be sensitive to ultraviolet A, which can be encountered from common light sources, such as unshielded fluorescent bulbs.

## 146.10 RARE ICHTHYLOSES

There are several very rare syndromes that include ichthyosis as a variable feature. The skin in these disorders is often the least involved feature.

### 146.10.1 Rare Ichthyoses Associated with Metabolic Disease

#### 146.10.1.1 Phytanic Acid Storage Disease.

**146.10.1.1.1 Clinical Features.** Phytanic acid storage disease Refsum disease was first described by Refsum in 1946, and the specific biochemical defect was first reported by Klenk and Kahike in 1963. The principal clinical features of the disease are early onset retinitis pigmentosa, peripheral motor and sensory polyneuropathy, cerebellar ataxia and high cerebrospinal fluid protein without cells. The onset is usually before 10 years of age but can occur later. Weakness and difficulty with walking, and failing vision, particularly night vision, are the most common initial complaints. Other clinical findings include cranial nerve involvement (anosmia, neurogenic hearing loss, abnormal papillary reflex), and skeletal abnormalities.

The skin is usually not severely involved, showing small white scales primarily of the extensor aspect of the trunk and extremities. The appearance most closely resembles ichthyosis vulgaris.

The disease has a progressive course with gradual deterioration, although many patients may show periods of remission. Severe exacerbation followed by partial recovery has been noted. Several deaths have been reported without known cause, and it has been speculated that a cardiac arrhythmia was responsible, since

**FIGURE 146-16** Trichothiodystrophy (TTD) hair shafts. Under polarized light microscopy TTD hair shafts show tiger tail banding pattern and shaft defects. Note the sharp breaks (trichoschisis).

ECG changes accompany the disease. Respiratory failure appears to be an important cause of death.

**146.10.1.1.2 Genetics.** The mode of inheritance of phytanic acid storage disease is autosomal recessive. It is caused by inherited defects in the metabolic pathway for phytanic acid, a dietary branched-chain fatty acid. The poorly metabolized phytanic acid accumulates in fatty tissues including myelin sheaths and in organs such as the kidney and liver. The enzyme defect in Refsum disease (MIM ID #266500) has been discovered to be phytanoyl-coenzyme A hydroxylase deficiency (Jansen et al., 1997), (*PHYH*, or *PAHX*, MIM ID \*602,026) or the gene encoding peroxin-7 (*PEX7*, MIM ID +601,757). Heterozygotes have about half the capacity for oxidizing phytanic acid as measured by tissue culture study although plasma levels are ordinarily normal. The infantile form (MIM ID #266510) of the disease is caused by mutations in (*PEX1*, MIM ID +602,136) or (*PEX2*, MIM ID +170,993), or (*PEX26*, MIM ID +608,666) peroxisome proteins.

**146.10.1.1.3 Management.** Therapy of the condition has been based on reduction of phytanic acid in the diet with a concurrent decrease in body phytanate levels (74). This assumes that the phytanate is responsible for the abnormalities. Patients so treated have shown an improvement in ichthyosis and neurological status symptomatically and by objective criteria, although it has not been possible to induce neurological changes in animals by loading with phytanates. Diets with less than 5 mg of phytanic acid are most effective. Care must be exercised to avoid weight loss which may rapidly mobilize tissue phytanates and raise blood levels. Plasma exchange has been reported to be effective in combination with diet since it allows removal of large amounts of phytanic acid.

#### **146.10.1.2 Chanarin–Dorfman Syndrome (Neutral Lipid Storage Disease with Ichthyosis).**

**146.10.1.2.1 Clinical Features.** Chanarin–Dorfman Syndrome (MIM ID #275630) is a rare inborn error of metabolism which presents as congenital ichthyosiform erythroderma and is characterized by intracellular accumulation of lipid droplets composed of triacylglycerol in most tissues. In addition to ichthyosis, multiple organs are involved. Manifestations include hepatosplenomegaly, myopathy, ataxia, neurosensory hearing loss, cataracts and mental retardation. The disease may present as a collodion baby with ectropion and eclabion. Peripheral blood smear shows lipid droplets in granulocytes (Jordans anomaly). Lipid droplets may also be seen in other cells including the basal keratinocytes of the epidermis.

**146.10.1.2.2 Genetics.** The pattern of inheritance is autosomal recessive and the disorder has been found to be caused by mutations in the CGI58 gene (abhydrolase domain-containing 5, *ABHD5*, MIM ID \*649780) (75). Adipose triglyceride lipase (ATGL) is a triacylglycerol hydrolase that promotes the catabolism of stored fat.

ATGL requires activation by CGI58. Therefore CGI58 functions as a lipolysis activator (76).

### **146.10.2 Rare Ichthyoses Associated With Neurological Disease**

#### **146.10.2.1 Sjögren-Larsson Syndrome.**

**146.10.2.1.1 Clinical Features.** Sjögren-Larsson syndrome (MIM ID #270200) was described in a group of 28 patients from a small area of Sweden in 1957 by Sjögren and Larsson. However, patients of various nationalities have been described. Infants tend to be pre-term, and at birth or within the first few months of life there are hyperkeratotic lesions, often generalized, with erythema clearly noted in some cases. While large lamellar scales are observed in some patients, in many there is skin thickening with marked accentuation of the ridge-like pattern of the skin reminiscent of lichenification (Figure 146-17) (77). The scalp, palms and soles are variably involved, the face sometimes, with ectropion rarely present. Itching is a frequent complaint. Intertriginous areas have been clear in some individuals. The ichthyosis is associated with a permeability barrier abnormality which has been attributed to abnormal lamellar body formation and secretion (78).

The neurological symptoms often begin as a delay in reaching motor milestones during the first few years of life due to spastic diplegia of the legs and less severe changes in the arms. Cognitive defects are common and vary from mild to severe. Characteristic retinal lesions which appear as glistening white dots around the fovea have been reported in most affected individuals and may

**FIGURE 146-17** Sjögren Larsson syndrome. Dark, ridge-like pattern of the skin.

appear as early as the second year. White matter disease may be present on brain MRI.

**146.10.2.1.2 Genetics.** Sjögren–Larsson Syndrome (SLS) is inherited as an autosomal recessive trait. The patients have deficient activity of the aldehyde portion (fatty aldehyde dehydrogenase (FALDH)) of the fatty alcohol: nicotinamide adenine denucleotide (NAD<sup>+</sup>) oxidoreductase (FAO) complex. FALDH catalyzes aldehydes derived from fatty alcohol metabolism and FAO catalyzes the overall oxidation of fatty alcohol to fatty acid. SLS patients are deficient in both FALDH and FAO activity. The gene encoding the human fatty aldehyde dehydrogenase (*ALDH3A2*; MIM ID \*609,523) is located on 17p 11.2 and mutations in this gene cause SLS (79). There is striking heterogeneity in the mutations in the FALDH gene which include deletions, insertions, missense mutations, splicing defects and rearrangements. Diagnosis can be made by measuring FALDH or FAO activity in cultured fibroblasts or leukocytes, or by DNA based methods such as screening for common mutations in selected populations or gene sequencing. Prenatal diagnosis can be made using DNA based or enzymatic studies of amniocytes or chorionic villous cells (80).

**146.10.2.2 Erythrokeratodermias.** The erythrokeratodermias are a heterogeneous group of disorders that are characterized clinically by hyperkeratosis and localized erythema. Two distinct clinical phenotypes are recognized, erythrokeratoderma variabilis and progressive symmetric erythrokeratoderma.

**146.10.2.2.1 Clinical Features.** Erythrokeratoderma variabilis (MIM #133200) is a rare disorder which usually presents during the first year but may occur later as ichthyosiform plaques and migratory red patches. The ichthyosiform plaques have different clinical character among different patients. Some patients have generalized involvement with persistent hyperkeratotic plaques over most of the body. Others have localized, sharply demarcated plaques (see Figure 146-18A) which may remain fixed for years. Both types have migratory red patches (see Figure 146-18B) which vary in size and may migrate over minutes to hours. The red areas may be triggered by trauma or temperature change and are symptomatic in

some patients, who often complain of burning. Hyperkeratosis of the palms and soles may be present. Erythrokeratoderma with a progressive spinocerebellar ataxia (Giroux-Barbeau type, MIM ID %133,190) has been described.

In progressive symmetric erythrokeratoderma (MIM #602036) the migratory red patches do not occur and only persistent erythematous hyperkeratotic plaques are present and they are for the most part limited to the extremities. They appear shortly after birth and progress slowly during childhood. They may regress after childhood.

Histological examination of the skin shows hyperkeratosis with a basket-weave appearance at the top and a compact one in the lower zone. There is hypergranulosis, papillomatosis, variable acanthosis and in some areas there may be a ‘church spire’ appearance. There is hyperplasia of the rete ridges with elongated capillaries and a peri-vascular lymphohistiocytic infiltrate in the dermis.

**146.10.2.2.2 Genetics.** Erythrokeratoderma variabilis is inherited as an autosomal dominant trait. The genetic locus for erythrokeratoderma variabilis was mapped to a locus on chromosome 1p32–34 (81), in a region of candidate connexin genes involved in epidermal differentiation. Mutations have been found in *GJB3* (*GJB3*; MIM ID +603,324) and *GJB4* (MIM ID \*605,425), the genes encoding connexins 31 and 30.3 respectively (82,83). However, the disorder is clinically heterogeneous even within families.

In a Japanese family with progressive symmetric erythrokeratoderma, a frameshift mutation in the loricrin gene on chromosome 1q21 was found (84). Loricrin is a major structural component of the cornified cell envelope, formed beneath the plasma membrane of stratified squamous epithelial cells during terminal differentiation. The progressive symmetric erythrokeratoderma is associated with keratoderma. This finding suggests that erythrokeratoderma variabilis and progressive symmetric erythrokeratoderma are distinct entities. However, in a more recent study, the same mutation in *GJB4* has been found in different families with either

**FIGURE 146-18** Erythrokeratoderma variabilis. (a) Sharply margined erythematous plaques with scaling accentuated at the borders. (b) Patients develop red patches, as shown here, which move over periods of minutes to hours.

erythrokeratoderma or progressive symmetric erythro-keratoderma (85).

### 146.10.3 Rare Ichthyoses Associated with Bone or Skeletal Disease

#### 146.10.3.1 Chondrodysplasia Punctata.

**146.10.3.1.1 Clinical Features.** Chondrodysplasia punctata is a heterogeneous group of disorders, first described by Conradi (1914), which has punctate calcifications that show up as stippling in radiographs. This may also be observed in other cartilagenous tissues such as the larynx and trachea. The disease has been classified into the Conradi-Hunermann type and a rhizomelic type, but several other forms have been described (see Ch. 165 Chondrodysplasias).

Cutaneous abnormalities are observed in about one fourth of the individuals and appear in the first few months of life. The eruption has a distinctive appearance (Figure 146-19) with a whorled pattern of thick white adherent scales on a background of erythematous skin. There is palmar and plantar hyperkeratosis, but nails and hair are normal. The cutaneous eruption disappears spontaneously by 3–6 months of age. Follicular atrophoderma and cicatricial alopecia have been observed in the site of the scaling.

The Conradi-Hünemann-Happle syndrome (CDPX2) (MIM #302960) is characterized by ichthyosis, chondrodysplasia punctata, cataracts and short stature. Clinically unaffected mothers or mothers with very mild disease expression may have somatic mosaicism or X-inactivation (86).

Histological examination of the skin shows marked hyperkeratosis and focal parakeratosis with invagination into the ostia of the pilosebaceous units. There is irregular elongation of the rete pegs with dilation of the dermal papillae and a relatively normal-appearing dermis.

**146.10.3.1.2 Genetics.** The Conradi-Hunermann syndrome is inherited as an X-linked dominant trait and mutations have been found in the emopamil binding protein (EPB, MIM ID \*300,205) (87,88). It has been demonstrated that there is an increased amount

of 8(9)-cholesterol and 8-dehydrocholesterol in tissue samples in X-linked dominant Conradi-Hunermann Syndrome, because of a mutation in *EBP*. An autosomal dominant (MIM %118650) type of chondrodysplasia punctata has also been described.

The rhizomelic type of chondrodysplasia punctata is a peroxisomal disorder. The rhizomelic type 1 (RCDP1) is autosomal recessive (MIM #215100) and caused by mutations in the peroxisomal biogenesis factor-7 gene, (*PEX7*, MIM ID +601,757). Type 2 (RCDP2, MIM ID #222765) is associated with a deficiency of dihydroxyacetonephosphate acyltransferase (MIM ID \*602,744). Type 3 (RCDP3, MIM #600121) is caused by mutations in the alkylidihydroxyacetonephosphate synthetase (alkyl-DHAP synthetase) gene. (*AGPS*, MIM ID \*603,051).

#### 146.10.3.2 CHILD Syndrome.

**146.10.3.2.1 Clinical Features.** CHILD Syndrome (MIM#308050) is an acronym that stands for Congenital Hemidysplasia with Ichthyosiform erythroderma and Limb Defects. The syndrome is characterized by unilateral erythema and scale, with a distinct demarcation in the middle of the trunk (Figure 146-20). The skin manifestations are present at birth or within the first week of life. Ipsilateral limb defects may vary from hypoplasia of fingers to a complete absence of an extremity. Ipsilateral hypoplasia of other parts of the skeleton along with defects in the brain and viscera are also seen. Punctate ipsilateral epiphyseal calcifications have also occurred.

**146.10.3.2.2 Genetics.** The ratio of female to male cases is approximately 19:1. The mode of inheritance is X-linked dominant. As a rule, it should affect exclusively girls because the underlying X-linked gene exerts a lethal effect on male embryos. Boys with the disease are assumed to have an early somatic mutation which allows them to survive. There is a mutation in the gene encoding NAD(P)H steroid dehydrogenase-like protein *NSDHL* (MIM ID \*300,275) (89,90), which affects cholesterol synthesis. Patients have also been described with mutations in the gene encoding EPB, the gene that also causes CDPX2 (90).

**FIGURE 146-19** Chondrodysplasia punctata. A newborn with a whorled pattern of scales on a red base. (Courtesy of Dr Nancy Esterly.)

**FIGURE 146-20** CHILD Syndrome. Unilateral erythema and scale with ipsilateral limb defects.

### 146.10.4 Rare Ichthyoses Associated with Hair Disease

#### 146.10.4.1 Netherton Syndrome.

**146.10.4.1.1 Clinical Features.** This autosomal recessive disorder (MIM ID #256500) is characterized by localized or generalized congenital ichthyosis, hair shaft abnormalities, immune deficiency and elevated IgE levels. The disease is usually present at birth with erythroderma and scaling. Infants may have failure to thrive or growth retardation and are at risk of postnatal dehydration, enteropathy and systemic infection, which can be fatal. Skin involvement can range from ichthyosis linearis circumflex (ILC), which is distinctive and appears as polycyclic and serpiginous erythematous lesions bordered by a double-edged scale on the trunk and proximal extremities (Figure 146-21) to a generalized ichthyosis resembling lamellar ichthyosis.

Patients have a specific abnormality of the hair called trichorrhexis invaginata (bamboo hair). The affected hairs show swelling in which there is a ball and socket invagination of the hair into itself, with the wider socket being more proximal (Figure 146-22). These hairs are fragile and break at the nodal swellings. Some patients are said to have normal hair or trichorrhexis nodosa or pili torti. Making a diagnosis in the neonatal period may be challenging since the pathognomonic features of trichorrhexis invaginata and ichthyosis linearis circumflexa are usually delayed until after infancy.

Some patients have an atopic dermatitis-like involvement of the skin with lichenification of the popliteal and antecubital fosse and the dorsum of the wrist. This may be associated with pruritus, allergic reactions and asthma.

**146.10.4.1.2 Genetics.** Netherton syndrome is caused by a mutations in the (*SPINK5*, MIM ID \*605,010) gene which encodes the serine protease inhibitor Kazal-type 5 protein (LEKTI) (91,92).

### 146.10.5 Rare Ichthyoses Associated with Eye and Ear Disease

#### 146.10.5.1 Keratitis–ichthyosis–Deafness (KID) Syndrome.

**146.10.5.1.1 Clinical Features.** KID syndrome (MIM ID #148210) is an ectodermal dysplasia characterized by a vascularizing keratitis, sensorineural hearing loss and an ichthyosiform disorder called erythrokeratodermia. Corneal neovascularization is progressive and may lead to visual impairment. Rather than the scaling typical of ichthyosis, skin involvement is often thickened with accentuated markings and localized to fixed plaques with a coarse surface (see Figure 146-23). These occur symmetrically and typically involve palmar and plantar surfaces. Patients may also have hair, nail and tooth abnormalities. There is increased susceptibility to mucous membrane and skin infections, which may be fatal in the newborn period. Chronic mucocutaneous

**FIGURE 146-21** Ichthyosis linearis circumflexa of Netherton syndrome. Serpiginous lesions with double-edged scale. (Courtesy of Dr James Stroud.)

**FIGURE 146-22** Netherton syndrome. (A) Trichorrhexis invaginata or 'bamboo' hair. (B) histopathology shows intussusception of hair in follicle. (Courtesy of Dr James Stroud.)

candidiasis may occur. Over time, chronic infection of hair bearing areas may lead to draining sinus tracts and scarring alopecia. Some patients have severe acneform eruptions and abscesses. Chronic paronychia may lead to nail dystrophy.

In some patients, there is a generalized mild hyperkeratosis of the skin with discrete erythematous plaques of the face (see Figure 146-24), extremities

**FIGURE 146-23** KID syndrome. Thickened, fixed plaques with a coarse surface.

and trunk with exaggerated skin markings, a variable verrucous appearance and some crusting. Rare patients have developed squamous cell carcinoma of the tongue.

**146.10.5.1.2 Genetics.** Most cases are inherited in an autosomal dominant pattern, but cases consistent with recessive inheritance have rarely been reported. The disorder has been found to be caused by dominant mutations in *GJB2* (MIM ID \*121,011), the gene that encodes connexin-26 (93). Connexins are transmembrane proteins that assemble to form gap junctions, which allow intercellular movement of molecules and ions.

**146.10.5.1.3 Management.** Infections of the skin, nails and mucous membranes are treated with appropriate antimicrobials, but are often resistant to clearing. Chronic infection of hair bearing areas may lead to scarring alopecia. Skin plaques of erythrokeratoderma are often resistant to treatment with agents typically used to treat ichthyosis.

## 146.10.6 Very Rare Ichthyosiform Disorders

There are a number of very rare ichthyoses which have a tissue or organ other than the skin which appears to be a singular feature. They have other abnormalities which can be found in OMIM under Clinical Synopsis. We have selected the disorders listed here because they have an identified mutated gene. Others can be found in OMIM. The disorders which we would like to identify are listed.

**146.10.6.1 Hair Defects.** #607626. Ichthyosis, leukocyte vacuoles, alopecia, and sclerosing cholangitis 3q28-q29, *CLDN1* gene (603,718).

#610765. Ichthyosis with hypotrichosis, autosomal recessive 11q24-q25, *ST14* gene (606,797).

**FIGURE 146-24** KID syndrome. Symmetrical fixed plaques on the face and scarring alopecia.

**146.10.6.2 Nail Defects.** #601952. Keratosis linearis with ichthyosis congenita and sclerosing keratoderma (KLICK syndrome), 13q12.3, *POMP* gene (613,386).

**146.10.6.3 Skin Fragility.** #173650. Kindler syndrome, 20p13, *FERMT1* (*KIND1*) gene (607,900).

**146.10.6.4 Neurological and Sensory Defects.** #308205. Ichthyosis follicularis, atrichia, and photophobia syndrome (IFAP syndrome), Xp22.12-p22.11, *MBPS2* (300,294) gene.

#609528. Cerebral dysgenesis, neuropathy, ichthyosis, and palmoplantar keratoderma syndrome (cednik syndrome) 22q11.2, *SNAP29* (604,202) gene.

#610768. Congenital disorder of glycosylation, type im; *CDG1M* 9q34.11, *TMEM15* gene (610,746).

#607721. Noonan-like syndrome with loose anagen hair 10q25, *SHOC2* gene (602,775).

#182600. Spastic paraplegia 3, autosomal dominant; *SPG3A* 14q11-q21, *SPG3A* gene (606,439).

**146.10.6.5 Multiple Organs Consistently Affected.** #608013. Gaucher disease, perinatal lethal, 1q21, glucocerebrosidase gene (*GBA*; 606,463).

#115150. Cardiofaciocutaneous syndrome 12p12.1 (*KRAS*, 190,070) 7q34 (*BRAF*, 164,757), 15q21 (*MEK1*, 176,872), 19p13.3 (*MEK2*, 601,263). These proteins are involved in a common RAS/ERK pathway regulating cell differentiation, proliferation and apoptosis. May have palmar plantar keratoderma (see Table 146-2).

#208085. Arthrogryposis, renal dysfunction, and cholestasis 15q26.1, *VPS33B* gene (608,552).

## 146.11 PHENOTYPE BY FUNCTION: ADVANCES IN UNDERSTANDING

### 146.11.1 Pathophysiological Mechanisms Underlying Ichthyoses

The past few decades have brought tremendous progress in identifying mutations causing a spectrum of ichthyosiform disorders. This has led to a better framework for understanding the pathophysiology that causes specific diseases. A relationship between different components of keratinocyte biology and keratinocyte pathology is emerging and may provide in a more mechanistically

**TABLE 146-4 Functional Classification of Selected Ichthyosiform Dermatoses**

Functional Abnormality	Disease
<b>Structural proteins</b>	
Cytoskeleton	
Filaggrin	Ichthyosis vulgaris
Keratins	Epidermolytic hyperkeratosis Ichthyosis bullosa of Siemans Pachyonychia congenita Palmar plantar keratodermas: Focal PPK with oral mucosa hyperkeratosis Striate PPK Type 1 & 3 Unna-Thost Type Vöerner Type
<b>Cornified Envelope Formation</b>	
Transglutaminase 1	ARCI/Lamellar ichthyosis
Loricrin	Progressive symmetric erythrokeratoderma Vohwinkel syndrome (mutilating keratoderma with ichthyosis)
<b>Intercellular junctions</b>	
Desmoplakin	Carvajal syndrome (PPK, woolley hair, cardiomyopathy)
Plakoglobin	Naxos disease
Desmoglein 1	Striate PPK Type 1
Desmoplakin	Striate PPK Type 2
<b>Lipid metabolism</b>	
Lipoxygenases	ARCI
Lipolysis activator	Chanarin-Dorfman
Steroid dehydrogenase	CHILD syndrome
Sterol isomerase	Conradi-Hunerman-Happle syndrome (chondrodysplasia punctata)
Phytanic acid catabolism	Refsum disease
Fatty alcohol & Fatty aldehyde metabolism	Sjögren-Larsson syndrome
Steroid sulfatase	X-Linked Ichthyosis
<b>Intercellular communication</b>	
Gap junction proteins (connexins)	Erythrokeratoderma variabilis Keratitits-Ichthyosis-Deafness syndrome Progressive symmetric erythrokeratoderma Vohwinkel syndrome with hearing loss
<b>Protein metabolism</b>	
Protease	IFAP (Ichthyosis follicularis, atrichia and photophobia syndrome)
Proteasome	KLICK
Protein trafficking	MEDNIK
Protease inhibitor	Netherton syndrome
Protease	Papillon-Lefèvre syndrome

focused classification of these disorders. Table 146-4 shows a classification of ichthyosiform dermatoses arrayed by functional abnormality. Further clarification of the aberrant mechanisms underlying these disorders may lead to more directed therapeutic approaches and

will undoubtedly lead to a better understanding of normal keratinocyte biology.

### 146.11.2 Prenatal Diagnosis

Prenatal diagnosis of several types of ichthyosis is widely available. Molecular diagnosis, which is best performed early in pregnancy, is preferable over the older methods of fetoscopy and fetal skin biopsy, which are now rarely used. For ichthyoses where the specific mutation in the family has been determined, chorionic villous sampling can be done in the first trimester or amniocentesis in the second trimester. FISH analysis can be used for the prenatal diagnosis of X-linked recessive ichthyosis, where most patients have a complete deletion of the STS gene. Prenatal diagnosis of TTD has been reported using defective DNA repair capacity (94). Prenatal diagnosis of Sjögren-Larsson Syndrome can be performed by molecular methods using fresh or cultured chorionic villi and in the past, has been done by using an enzymatic assay for fatty aldehyde dehydrogenase activity (FALDH) in cultured amniocytes or chorionic villus fibroblasts (95,96). In the setting of an autosomal recessive disorder where the molecular defect is known and relatives may be at risk, carrier detection can be performed. Genetests ([www.ncbi.nlm.nih.gov/sites/genetests/](http://www.ncbi.nlm.nih.gov/sites/genetests/)) is a source of available testing resources.

### Biographies

**Howard Baden** is a professor of Dermatology at Harvard Medical School, and a Dermatologist at the Massachusetts General Hospital. He is a member of the Cutaneous Biology Research Center located in the Massachusetts General Hospital, which was established in 1989. His research was concerned with differentiation of epidermis and the skin appendages. He was responsible for defining the basis of a number of human genetic disorders. As a clinician Dr Baden was recognized for his expertise with genetic disorders of the skin, most particularly of the epidermis and hair and nails. He has published a number of papers and reviews in this field and was an author in the prior issue of the *Principles and Practice of Medical Genetics*.

**Dr DiGiovanna** is currently in the Dermatology Branch of the National Cancer Institute, NIH, serves as a consultant to the Division of Dermatological and Dental Drugs of the Food and Drug Administration, and since 1980 has held various positions at the NIH. He was previously the Director of Dermatopharmacology and Professor in the Department of Dermatology at the Warren Alpert Medical School of Brown University. His areas of interest include the efficacy and toxicities of systemic retinoids, and the clinical phenotypes and underlying causes of inherited skin disorders. He has worked extensively on the clinical characterization and underlying genetic causes of the disorders of cornification, skin cancer predisposition syndromes, and the disorders of DNA repair. He has published over 125 original articles, 25 book chapters and lectured widely at national and international conferences.

Thomas Jefferson University, Philadelphia, USA

### GLOSSARY

- Desmosomes** – (Greek: desmos, band; soma, body)  
Localized adhesion complexes on the lateral sides of plasma membranes in simple and stratified squamous epithelia. They are the major cell–cell adhesion complexes in the epidermis, anchoring keratin intermediate filaments to the cell membrane.
- Hemidesmosomes** – A structure that stabilizes the attachment of epidermis to the basement membrane. The molecular components of desmosome and hemidesmosome are different.
- Focal adhesions** – Specific types of large macromolecular assemblies through which both mechanical force and regulatory signals are transmitted between the extracellular matrix and the cell.

### 147.1 INTRODUCTION

Epidermolysis bullosa (EB) is a clinically and genetically heterogeneous group of genodermatoses characterized by mucocutaneous blistering and chronic epithelial fragility (1). The characteristic symptoms, skin blistering and erosions, result from intraepidermal or dermo-epidermal tissue separation caused by minor friction or trauma. EB occurs across all populations throughout the world, but no precise numbers exist on its global prevalence or incidence. Data from a number of European countries suggest a prevalence of  $24\text{--}49 \times 10^{-6}$  (References (2,3), and J. Bauer, Salzburg and M. Jonkman, Groningen, personal communications), and an incidence of 1 in 39,000 has been reported (German EB Network registry, [www.netzwerk-eb.de](http://www.netzwerk-eb.de)). In the US National EB Registry, a prevalence of  $8.22 \times 10^{-6}$  was calculated for the year 1990 (4). This figure was believed to be low due to the fact that the registry did not capture the mildest forms of EB. Similarly, other studies have emphasized the fact that a large number of patients with relatively mild forms of EB were found only when family members of more severely

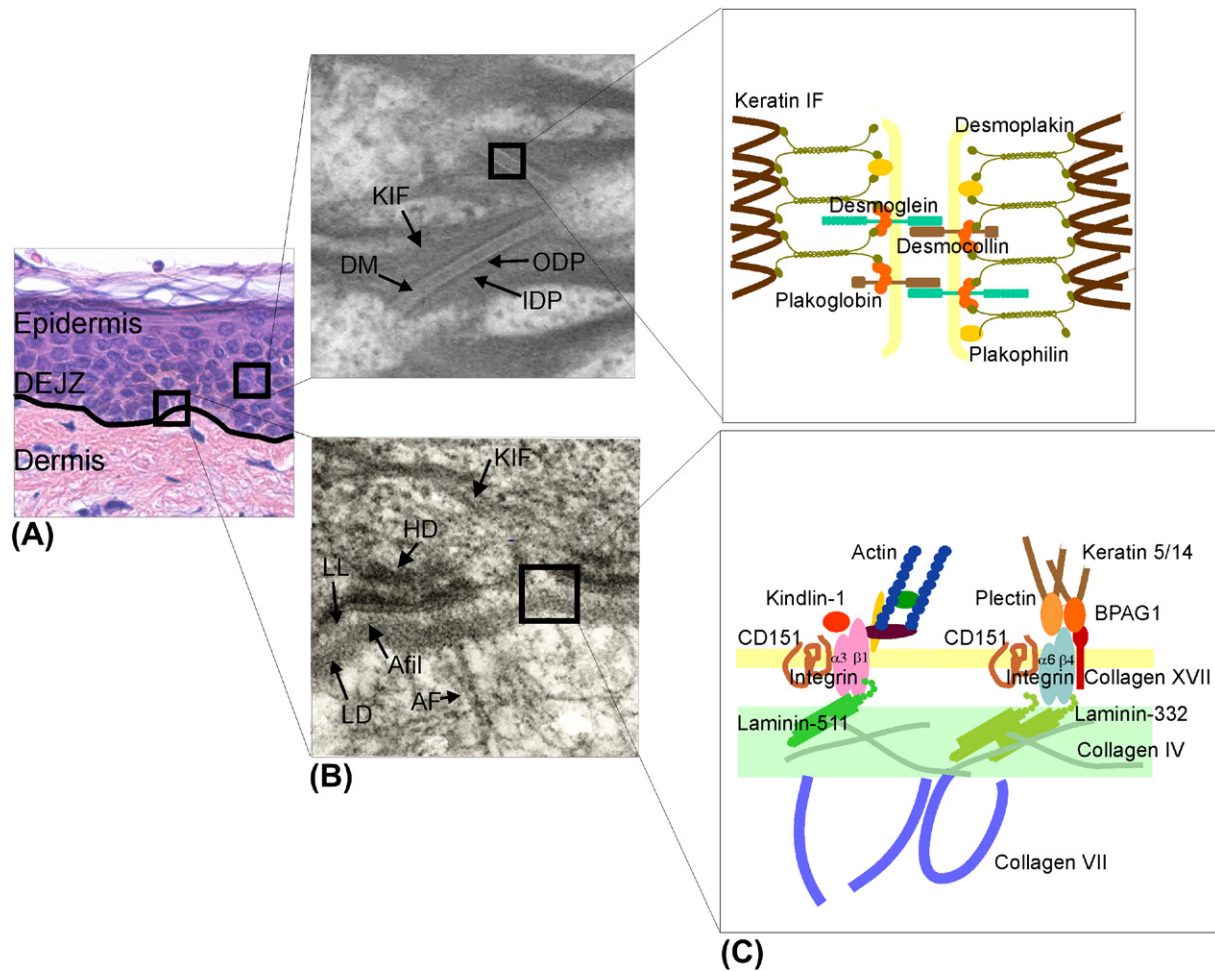

affected patients were examined. Many of them had gone unrecognized, since these patients regarded their skin as quite normal and had never seen a dermatologist.

### 147.2 MOLECULAR BASIS OF EPIDERMAL AND DERMO-EPIDERMAL ADHESION

The cutaneous basement membrane zone, which attaches the lower layer of epidermis to the underlying dermis in the skin, is structurally and functionally altered in EB. In rare cases, cell–cell adhesion in the upper layers of epidermis is perturbed. Electron microscopic studies have been instrumental in visualizing the ultrastructural characteristics of the cutaneous basement membrane zone and the adhesion complexes that attach the skin layers, including the desmosomes, hemidesmosomes, the basement membrane proper, anchoring filaments and anchoring fibrils (5). They lend the skin its resistance against environmental factors, including mechanical, physical and microbial insults (6). The desmosomes anchor cytoskeletal intermediate filaments to cell–cell junctions, and at the cutaneous basement membrane zone, the hemidesmosome-anchoring filament complexes link the cytoskeleton within basal keratinocytes with the extracellular basement membrane. This, in turn, interacts with anchoring fibrils, which attach the lower part of the basement membrane to the underlying dermis (7). At least 16 genes encoding proteins of the epidermis or the cutaneous basement membrane zone are involved in the pathogenesis of EB (Table 147-1). In order to understand the molecular basis of the epidermal and dermo-epidermal adhesion and their abnormalities in EB, a summary of these structures is given below and in Figure 147-1.

#### 147.2.1 Epidermal Cell–Cell Adhesion

The desmosomes are intercellular junctions in tissues exposed to mechanical stress, such as the skin,

**FIGURE 147-1** Morphologic and ultrastructural features of human skin. (A) HE staining of normal skin with epidermis, dermis and the dermo-epidermal basement membrane zone (DEJZ). Details of the marked areas are shown in panel B as transmission electron micrographic pictures and in panel C as schematic representations of the molecular components. (B) TEM depicting the desmosomes (upper panel) and DEJZ (lower panel). The critical structures are indicated by arrows: keratin intermediate filaments (KIF), outer dense plaque (ODP), inner dense plaque (IDP), dense midline (DM), hemidesmosomes (HD), lamina lucida (LL), and, anchoring filaments (Afil), lamina densa (LD), anchoring fibrils (AF). (C) The critical disease relevant molecular components of desmosomes (upper panel) and DEJZ (lower panel) are depicted schematically. (EM courtesy of Dr Ingrid Hausser, Heidelberg).

myocardium, bladder and gastrointestinal mucosa (8). In the epidermis, desmosomes are located at keratinocyte plasma membranes tethering the keratin intermediate filaments to the plasma membrane (9). Ultrastructurally, they consist of an outer electron-dense plaque adjacent to the plasma membrane, an electron-lucent zone, and an inner dense plaque (10,11) (Figure 147-1B). The adjacent cells are separated by an extracellular domain, ~30nm wide, which contains a dense midline. Each plaque consists of a supramolecular protein complex of components belonging to three protein families: cadherins, armadillo proteins, and plakins (Figure 147-1C). The desmosomal cadherins, desmogleins and desmocollins, are transmembrane proteins. The extracellular domain of these proteins consists of cadherin repeats separated by calcium binding motifs, and the transmembrane stretch is followed by an intracellular domain at the cytoplasmic face of the plasma membrane (8). The

extracellular domains interact to form the adhesive interface, whereas the cytoplasmic tails bind to the armadillo proteins, plakoglobin ( $\gamma$ -catenin) and plakophilins 1–4. These proteins regulate the assembly of the desmosomal components and attach desmoplakin and keratin filaments to the desmosome.

Plakoglobin is found at both desmosomes and adherence junctions; it functions as a scaffold for a number of binding partners, including desmosomal cadherins, E-cadherin and desmoplakin (12). Plakophilins are expressed in a tissue- and differentiation-specific manner, and plakophilin 1 and 2 are also found in the nucleus, suggesting specific regulatory roles for these proteins. The N-terminus of plakophilin 1 binds desmoglein 1, desmoplakin and keratin intermediate filaments, and it plays a key role in the assembly of the desmosomes (13). Desmoplakin links the keratin cytoskeleton to the armadillo proteins and cadherins. It is the most abundant

component of the desmosomes and consists of a central  $\alpha$ -helical coiled-coil rod domain, which is flanked by globular N- and C-termini. The N-terminal domain binds plakoglobin and plakophilins. The stable molecular interactions between desmosomes and intermediate filaments provide a high degree of resistance to mechanical forces. Apart from the adhesion function, emerging *in vivo* data suggest that desmosomal molecules also play a role in epidermal cell signaling (10).

### 147.2.2 Cell–Matrix Interactions

The hemidesmosomes mediate the attachment of the basal keratinocytes of the epidermis to the underlying basement membrane (Figure 147-1B). At the molecular level, they represent supramolecular assemblies of distinct intracellular and transmembrane proteins (Figure 147-1C). Two intracellular plakin homologs, BPAG1 (bullous pemphigoid antigen 1, also known as BP230 or the 230-kD bullous pemphigoid antigen) and plectin are components of the hemidesmosomal inner plaque. The homology of these plakins implies that these proteins bind keratin intermediate filaments. Different plectin isoforms expressed in epithelia and muscle tissues have been characterized (14,15). The two transmembrane components of the hemidesmosomes are collagen XVII (BPAG2 or BP180, the 180-kD bullous pemphigoid antigen) and  $\alpha 6 \beta 4$  integrin. Collagen XVII is a prototype of the transmembrane collagens, i.e. type II transmembrane proteins with a collagenous ectodomain (16). This cell surface receptor can interact with several binding partners. The intracellular ligands of collagen XVII are plectin, BPAG1 and  $\beta 4$  integrin, and its extracellular ligands are  $\alpha 6$  integrin and laminin-332 (17). The ectodomain of collagen XVII binds laminin-332 and is essential for the adhesion of the hemidesmosomes to the underlying basement membrane (17). The ligands of  $\alpha 6$  integrin include CD151, collagen XVII and laminin-332 (18).

Apart from hemidesmosomes, other adhesion molecules at the basolateral plasma membrane of basal keratinocytes include proteins found in focal adhesions *in vitro*, e.g. integrin  $\alpha 3 \beta 1$ , transmembrane collagen XIII, and kindlin-1 (also known as fermitin family homolog 1) (Figure 147-1C). These are involved in tethering the actin cytoskeleton to cell-matrix adhesions as alternative means to anchor basal epithelial cells to the basement membrane (18). A stabilizer of integrin functions at the cutaneous basement membrane zone, CD151, is a member of the tetraspanin family of cell surface proteins. It forms complexes with  $\alpha 3 \beta 1$  and  $\alpha 6 \beta 4$  integrins at the basolateral surface of basal keratinocytes (19).

The cutaneous basement membrane zone provides firm attachment between the epidermis and the reticular dermis. Underneath the plasma membrane of basal keratinocytes is the basement membrane proper, which

ultrastructurally consists of two layers, as shown by electron microscopy (Figure 147-1B). The zone adjacent to the epidermal basal cells is the 25–50 nm wide lamina lucida. This zone is traversed by anchoring filaments, which originate in the plasma membrane of basal cells and insert into the lamina densa and thus secure the epithelial cells to the underlying basement membrane. The anchoring filaments consist of laminin-332 and collagen XVII. The lower zone, the lamina densa, appears as an electron-dense amorphous structure of 20–50 nm in width. Its major molecular components are collagen IV, nidogens, perlecan, and laminins, which all can polymerize to network structures (20,21).

From the lamina densa, anchoring fibrils, which by electron microscopy appear as cross-striated condensed fibrous aggregates with frayed ends, extend into the dermis (Figure 147-1B, C). The proximal end inserts into the lamina densa, and the distal end is integrated into the fibrous network of the dermis or loops back to the basement membrane, thus providing anchorage of the basement membrane to the reticular dermis.

The detailed knowledge on the molecular components and their suprastructures in the epidermis and the cutaneous basement membrane zone is very helpful for diagnostic evaluation of EB skin biopsy specimens by immunofluorescence (IF) staining or transmission electron microscopy (TEM). An IF staining with antibodies to the individual marker proteins indicates the localization of these molecules at the cutaneous basement membrane zone and allows determination of the blistering level in EB (Figure 147-2). Furthermore, the intensity of the IF signal can be indicative of an altered or missing protein and thus helpful for determination of a candidate gene and the subtype of EB (see below).

### 147.3 CLASSIFICATION

The latest international consensus classification defines four major EB types based on the ultrastructural level of tissue separation (1): EB simplex (EBS), junctional EB (JEB), dystrophic EB (DEB), and the Kindler syndrome (KS) (Figure 147-2). These can be further separated into subtypes. In addition to the level of tissue separation, clinical severity and the inheritance pattern were applied as criteria for the major subtypes (Table 147-1). Further clinical and molecular genetic characteristics could distinguish more than 30 minor subtypes of EB (1), although many of these represent allelic variants and it remains questionable whether they should be considered as distinct subtypes.

In EBS, the cleavage occurs within the epidermis. This category is subdivided into two major subtypes: (a) suprabasal with cleavage within the upper epidermal layers and (b) basal with cleavage within in the basal keratinocytes at the bottom of the epidermis. Mutations in the genes encoding desmoplakin, plakophilin-1 and plakoglobin underlie suprabasal EBS. In the majority of

**FIGURE 147-2** The classification of EB is based on the level of skin cleavage, and relies on IF mapping and TEM findings. (A) In the left panel, indirect IF staining of control normal human skin with antibodies to desmoplakin (green) and collagen IV (red) is shown. Details of the demarked area are shown in TEM in the right panel. The levels of cleavage in the main EB types are indicated by arrows. (B) Skin biopsies from patients with JEB and DEB were immunostained with antibodies to collagen IV. The blister is marked by an asterisk. Note the staining in the floor and the roof of the blister, respectively. (C) Note the irregular staining pattern of collagen IV in KS skin (left), consistent with the reduplication of the basement membrane shown in TEM (right). Bars = 50  $\mu$ m. (TEM courtesy of Drs. Ingrid Hausser, Heidelberg, and Ivelina Yordanova, Pleven).

basal EBS cases, keratin 5 and 14 are mutated, and, consequently, keratin intermediate filaments are structurally and functionally altered. In more rare forms of EBS, intracellular proteins or protein domains within the hemidesmosomes are mutated or missing, including plectin, BPAG1, the intracellular domain of integrin  $\beta$ 4, or collagen XVII.

In JEB, dermo-epidermal separation takes place along the lamina lucida within the basement membrane zone, and the hemidesmosome-anchoring filament complex appears altered. Transmembrane and extracellular proteins of the hemidesmosomes and the anchoring filaments

are affected: collagen XVII, laminin-332 or integrin  $\alpha$ 6 $\beta$ 4. The separation into major JEB subtypes relies on the severity of the disorder. JEB-Herlitz, caused by lack of laminin-332, has a lethal course due to extreme fragility of the skin and mucous membranes, whereas JEB-non-Herlitz (also called JEB-other) exhibits milder, yet variable degree of chronic skin fragility but essentially a normal lifespan.

In DEB, blistering takes place at the level of the anchoring fibrils in the uppermost dermis. The anchoring fibrils can be either completely absent, reduced in number or, if present, ultrastructurally altered. Mutations in the gene for collagen VII, *COL7A1*, underlie both dominant and recessive forms of DEB.

KS is considered to be a distinct EB subtype because, in contrast to the other major types of EB described above, there are typically multiple cleavage planes— intraepidermal, junctional, or sub-lamina densa (1). Mutations in the *FERMT1* gene, which encodes kindlin-1, a keratinocyte protein in the focal adhesion complexes, are the underlying cause of KS.

## 147.4 CLINICAL FEATURES

### 147.4.1 EB Simplex

#### 147.4.1.1 Suprabasal EBS

**147.4.1.1.1 Lethal Acantholytic EB.** Lethal acantholytic EB (MIM 609638) is an extremely rare subtype caused by loss-of-function mutations in the desmoplakin gene, *DSP*. Severe mucocutaneous fragility and epidermolysis are already evident during delivery and rapidly progress to extensive erosions (22). The phenotype in four published cases is somewhat variable but includes universal alopecia, nail loss or neonatal teeth (23–25). Massive transcutaneous fluid loss leads rapidly to early demise (23–25). Histology reveals suprabasal clefting and acantholysis throughout the spinous layer of the epidermis. Immunostaining for desmoplakin is negative, or a punctuated intercellular pattern may be observed. TEM demonstrates keratin intermediate filaments severed from desmosomes.

It should be noted that mutations in the *DSP* gene can cause a spectrum of phenotypes with or without skin fragility (26). Two patients were described with trauma-induced skin blistering, palmoplantar keratoderma, alopecia and early onset cardiomyopathy (27,28). These phenotypes were due to loss-of-function or truncating desmoplakin mutations. In contrast, compound heterozygosity for nonsense and missense mutations was shown to cause skin fragility, woolly hair and palmoplantar keratoderma, with or without associated cardiomyopathy (29,30). In all cases, morphological examination of the skin revealed adhesion defects involving the entire stratum spinosum.

**147.4.1.1.2 Lethal Congenital EB.** This new entity belonging to the suprabasal EBS subtype is characterized by extensive areas of superficially eroded skin at birth,

**TABLE 147-1 Classification of EB, Causative Genes, Affected Proteins and Mode of Inheritance**

Major EB Types	Major EB Subtypes	Gene, MIM	Protein	Inheritance
EBS	Suprabasal	<i>DSP</i> , 125647	Desmoplakin	AR

AR, autosomal recessive; AD, autosomal dominant.

absence of the scalp hair and onycholysis, and has been reported in only one individual so far (31). The condition rapidly progressed to a generalized epidermolysis with massive fluid loss through the epidermis, which apparently lacked any barrier function, and produced a lethal outcome within two weeks. Null mutations in the *JUP* gene encoding plakoglobin cause this suprabasal EBS subtype. Other mutations in the *JUP* gene are known to be associated with cardiac abnormalities (26), however, in this case ultrasound revealed normal morphology and function of the heart. Possibly, the early demise of the patient prevented clinical manifestations of cardiac anomalies. Histopathology of the skin showed pronounced acantholysis and cleavage in the suprabasal epidermis, with loss of upper spinous, granular and horny layers. Basal keratinocytes were attached to the basement membrane, but had little or no contact to neighboring and suprabasal cells. TEM revealed absence of desmosomes on the lateral aspects of basal cells and around all spinous cells.

Similar to the cases of desmoplakin deficiency, *JUP* mutations have also been associated with a spectrum of phenotypes. A phenotype consisting of mild skin fragility, accompanied by woolly hair and palmoplantar keratoderma, caused by homozygous mutations in the 5' region of *JUP* was recently described in three unrelated patients (32). Trauma-induced skin blistering, predominantly on the extremities, was noted during the first month of life (32,33). Nails were normal at birth but subsequently became dystrophic. No cardiac anomalies were disclosed by the age of 14 years. IF staining demonstrated marked reduction of plakoglobin expression, whereas TEM revealed widening

of intercellular spaces between keratinocytes extending from the suprabasal layer to the granular layer, and hypoplastic desmosomes which were reduced in number.

**147.4.1.1.3 Ectodermal Dysplasia–Skin Fragility Syndrome.** The ectodermal dysplasia–skin fragility syndrome (MIM 604536) is caused by loss-of-function mutations in the *PKP1* gene encoding plakophilin 1 (34,35). Clinical features include trauma-induced or spontaneous erosions of the skin, hypotrichosis or woolly hair, dystrophic nails, and painful fissuring with palmoplantar keratoderma (35). Typically, affected children have growth abnormalities. The morphological characteristics include dysadhesion of the cells in the suprabasal layers of the epidermis or a complete separation of the epidermis above the upper spinous layers. IF staining with plakophilin 1 antibodies is negative. TEM reveals loss of cell–cell adhesion in the lower suprabasal layers as well as few, relatively small desmosomes. A very similar phenotype associated with cardiomyopathy was reported to be caused by truncating desmoplakin mutations (28).

#### 147.4.1.2 Basal EBS

**147.4.1.2.1 Basal EBS Caused by Keratin 5 or 14 Mutations.** Basal EBS is the most common EB subtype, accounting for about one half of all cases (36). Blisters result from disintegration of the basal keratinocytes in the lowermost epidermis as a result of friction and trauma to the skin. Most cases are inherited in an autosomal dominant manner. Blistering starts at birth or soon thereafter, and the clinical spectrum ranges from mild localized to severe generalized blistering (Figure 147-3). The blisters heal without scarring, although secondary trauma and infection can cause milia,

**FIGURE 147-3** Clinical features of EBS basal. (A) EBS localized in a 45-year-old man with the heterozygous *KRT14* mutation p.V268D. (B) EBS Dowling–Meara due to *KRT14* mutation p.R125C in an infant. Note disseminated herpetiform blisters. (C) The 33-year-old of the girl shown in panel B has the same mutation, but only mild toenail dystrophy as a clinical symptom. (D) Severe generalized blistering in a 40-year-old patient with EBS Dowling–Meara caused by the *KRT5* mutation p.E477K. (E) Severe plantar keratosis in a 35-year-old patient with EBS Dowling–Meara caused by the *KRT14* mutation p.Y129D. (F) Generalized blistering in a patient with autosomal recessive EBS caused by the homozygous *KRT14* mutation p.W305X. (G) EBS with mottled pigmentation caused by the *KRT5* mutation p.P25L in a young woman.

mild scars and nail dystrophy. Particularly in cases with generalized blistering, painful palmoplantar hyperkeratosis can develop. The most common subtypes are EBS localized (MIM 131800), EBS Dowling–Meara (MIM 131760), and EBS–other generalized (MIM 131900). In addition, EBS with mottled pigmentation (MIM 131960) and migratory circinate EBS (MIM 609352) represent clinically distinct but rare subtypes. Autosomal recessive EBS (MIM 601001) due to *KRT14* null mutations is rare in Western populations, but accounts for about one-third of EBS cases in the Middle East (37).

In all forms of EBS, IF staining of skin with antibodies to keratins and cutaneous basement zone proteins demonstrates splitting within the lowermost epidermis. However, in about 60% of cases, no skin cleavage is found in the biopsy specimens, and the IF is not conclusive. Negative keratin 14 staining is indicative of recessive EBS. Mutations in either the gene for keratin 5, *KRT5*, or for keratin 14, *KRT14*, underlie most cases of basal EBS (1). It should be noted that keratin 5 and 14 mutations may cause a spectrum of disorders manifesting with reticulate pigmentation, such as Dowling–Degos disease (MIM 179850), dermatopathia pigmentosa reticularis (MIM 125595), or

the Naegeli–Franceschetti–Jadassohn syndrome (MIM 161000), all without skin blistering (38).

**147.4.1.2.2 Basal EBS Caused by Plectin Defects.** Plectin deficiency may cause three different, rare EBS subtypes: EBS with muscular dystrophy (MIM 226670), EBS with pyloric atresia (MIM 612138), both inherited in an autosomal recessive manner, and EBS Ogna (MIM 131950), which has an autosomal dominant inheritance (39).

EBS with muscular dystrophy manifests with congenital generalized blistering accompanied with late-onset progressive muscular dystrophy (Figure 147-4). The skin lesions heal without scarring, but atrophy and nail dystrophy are present. Additional phenotypic features include mild palmoplantar keratoderma, dental anomalies, corneal involvement, extensive mucosal erosions and urethral strictures. Age of onset and the extent of muscular dystrophy are variable, but in most cases the patients become wheelchair-bound in their twenties and can die prematurely. Thus far, only a few patients with EBS with pyloric atresia due to plectin mutations have been reported (39–41). All exhibited widespread congenital absence of skin together with pyloric atresia noted at birth and died from complications of the disease shortly thereafter.

**FIGURE 147-4** EBS with muscular dystrophy. Hemorrhagic blisters and involvement of the toenails in a 3-year-old patient with EBS with muscular dystrophy caused by compound heterozygosity for *PLEC* mutations c.4643\_4667dup and c.7120C>T. (Photo courtesy of Dr Slobodna Murat-Susic, Ljubljana).

Both EBS with muscular dystrophy and EBS with pyloric atresia are caused by mutations in the *PLEC* gene. The most severe forms of EBS with muscular dystrophy are associated with premature termination codon mutations, while a definitively milder form has been encountered as a result of an in-frame 9-bp deletion mutation (42). IF staining with plectin antibodies can show complete absence of this protein, or the staining is reflecting the type of mutations in the *PLEC* gene. TEM of skin reveals cleavage within basal cells just above the hemidesmosomes, with hypoplastic attachment plates and impaired keratin filament insertion into the inner hemidesmosomal plaque. Recently, it was suggested that mutations within *PLEC* exon 31 and loss of the full-length plectin with residual expression of the rodless plectin isoform leads to EBS with muscular dystrophy. In contrast, mutations located outside exon 31 lead to complete loss or marked attenuation of both the expression of full-length and rodless variants of plectin and underlie the more severe EBS with pyloric atresia phenotype (43). The same authors reported the first case of EBS associated with both pyloric atresia and muscular dystrophy, caused by compound heterozygous premature termination codon-causing mutations located within exon 32 of *PLEC* (44).

Only a few families with EBS Ogna have been reported. All patients carry the same heterozygous *PLEC* mutation, p.R2000W (45). EBS Ogna manifests with seasonal acral blistering with onset in infancy, generalized tendency to skin bruising and onychogryphosis (45). IF staining with most plectin antibodies is positive, whereas particular monoclonal antibodies recognizing epitopes within the rod domain do not immunoreact with skin samples of EBS Ogna patients (43).

Recently, a mutation in exon 1f of *PLEC*, leading to disruption of the plectin isoform 1f was associated with

autosomal recessive limb-girdle muscular dystrophy (MIM 613723), without skin manifestations (46).

#### 147.4.1.3 Rare EBS Subtypes

**147.4.1.3.1 Recessive EBS Caused by *BPAG1* Mutations.** In one patient, recessive EBS was caused by a homozygous nonsense mutation in the dystonin gene (*DST*) that encodes the epithelial isoform of bullous pemphigoid antigen 1, BPAG1-e (also known as BP230) (47). Clinical features included lifelong generalized blistering and erosions. In addition, the patient had mild episodic neurological symptoms, but it remained unclear whether these were a manifestation of the *DST* mutation, or reflected a concomitant disease of the patient, a cerebral arteriopathy, due to a heterozygous mutation in *NOTCH3* gene. The *DST* mutation led to loss of hemidesmosomal inner plaques and a complete absence of immunostaining for BPAG1-e, as well as reduced labeling with antibodies to plectin,  $\beta 4$  integrin, and collagen XVII (47).

**147.4.1.3.2 EBS Caused by Mutations in the Intracellular Domain of Transmembrane Proteins.** Rare cases of EBS have been shown to result from mutations altering the intracellular domain of hemidesmosomal transmembrane proteins,  $\beta 4$  integrin and collagen XVII. Deletions in the *ITGB4* and *COL17A1* genes have been shown to cause intracellular cleavage low in the basal keratinocytes due to hampered attachment of keratin intermediate filaments to the hemidesmosome (48–50). The clinical features are consistent with EBS, and there was no history of pyloric atresia (48–50).

### 147.4.2 Junctional EB

**147.4.2.1 JEB-Herlitz.** JEB-Herlitz (MIM 226700) is the most severe JEB subtype and usually leads to death within the first two years of life. Extreme mucocutaneous fragility, erosions and blistering from birth are characteristic (Figure 147-5A). Extremities, the scalp and the face are usually affected early on, together with oral and respiratory mucous membranes (Figure 147-5B). Blisters heal without scars, but mild atrophy may occur after recurrent lesions. At some stage the healing ceases and chronic erosions and exuberant granulation tissue dominate the skin phenotype. Nails are lost and paronychia-like lesions with granulation tissue at the fingertips are characteristic (Figure 147-5C). Enamel defects, particularly pitting and hypoplasia, are common, but dental growth is normal. Laryngeal involvement with blisters and strictures causing upper airway obstruction may become life threatening. Eventually, fluid and protein loss, combined with poor feeding, cause severe systemic complications and, ultimately, organ failure. IF staining of the skin reveals absence or significant reduction of laminin-332. Null mutations in the *LAMB3*, *LAMC2* and *LAMA3* genes, which encode the three constituent polypeptide chains of the laminin-332 molecule, underlie this subtype.

**FIGURE 147-5** Clinical presentation of JEB-Herlitz. (A) A newborn with JEB-Herlitz. Severe involvement of areas exposed to mechanical trauma. (B) Extensive, poorly healing granulomatous facial lesions in JEB-Herlitz. (C) Typical nail involvement.

**147.4.2.2 JEB-Non-Herlitz (JEB-Other).** The most common JEB subtype, collectively called JEB-non-Herlitz (or JEB-other) (MIM 226650), encompasses a spectrum of phenotypes ranging from localized to generalized skin blistering, with onset at birth or later in life (51) (Figure 147-6). In addition to blisters, typical clinical symptoms include hypopigmentation at the sites of blistering, mild skin atrophy, and dystrophy or loss of nails (Figure 147-6A–C). In some cases, parietal or even total alopecia develops in the course of the disease (Figure 147-6D). Dental abnormalities are typically observed in form of generalized enamel hypoplasia (Figure 147-6E,F) leading to susceptibility to caries and loss of teeth early in life. Extracutaneous involvement is not common. TEM demonstrates tissue separation along the lamina lucida and the presence of poorly developed hemidesmosomes. IF staining of the skin reveals junctional blistering and positive, yet frequently attenuated, laminin-332 staining, and/or reduced or absent collagen XVII staining. This JEB subtype is genetically heterogeneous: mutations in the laminin-332 genes *LAMB3*, *LAMA3* and *LAMC2*, or in the collagen XVII gene, *COL17A1*, can underlie these phenotypes.

EB nevi are large, often irregular melanocytic lesions initially described in JEB-non-Herlitz (52). They may manifest clinical, histological and dermatoscopic features suggestive of melanoma (53). Although it is not clear whether EB nevi are melanoma precursor lesions, regular follow-up is recommended (52). It should be noted that EB nevi might occur in patients with all EB variants (52) (Figure 147-7).

**147.4.2.3 JEB with Pyloric Atresia.** JEB with pyloric atresia (MIM 226730) is a relatively rare EB subtype, characterized by skin blistering and pyloric atresia, which may be suggested prenatally by gestational hydramnion (54). The severity of the disease can be variable. At birth, the condition can be dramatic and perinatally lethal, in spite of surgical correction of pyloric atresia, while mild JEB with pyloric atresia has a favorable prognosis after surgery. In some cases, skin involvement can be minimal, sometimes with late onset of acral blistering, nail dystrophy and/or enamel

**FIGURE 147-6** Clinical features of JEB-non-Herlitz. (A) A 16-year-old male compound heterozygous for the *LAMA3* mutations p.Q738X and p.A1484V. Note the partial dystrophy of the finger nails. (B) The same patient exhibits linear scars in traumatized areas of the skin. (C) Blistering, hypopigmentation, nail loss and dystrophy in a 37-year-old woman with JEB-non-Herlitz due to *COL17A1* mutations p.M1T and p.R1226X. (D) Extensive non-scarring alopecia in the patient shown in panel C. (E) Enamel pitting in the patient shown in panel A. (F) Careful examination of his healthy mother revealed involvement of the teeth, but no skin or nail manifestations.

hypoplasia. Disease-causing mutations have been discovered in the genes coding for  $\beta 4$  and  $\alpha 6$  integrin, *ITGB4* and *ITGA6*, with the majority of mutations

**FIGURE 147-7** EB nevi. (A) A 7-year-old patient with EBS. (B) A 28-year-old patient with JEB-other, and (C) in a 5-year-old patient with DEB.

involving the integrin  $\beta 4$  subunit (54,55). IF staining of the skin reveals junctional blistering, and attenuated staining for  $\beta 4$  and/or  $\alpha 6$  integrin (54). Interestingly, the severity of pyloric atresia may also be variable and can be absent in some cases with skin manifestations but with a family with history of JEB with pyloric atresia (56). It is apparent, therefore, that factors other than the mutations in the  $\alpha 6\beta 4$  integrin genes are likely to contribute to this phenotype (57).

**147.4.2.4 JEB with Renal and Respiratory Involvement.** Recently mutations in the integrin alpha3 gene (*ITGA3*) were identified in three children with a multi-system disorder comprising skin, renal and respiratory involvement. The disease first manifested with respiratory distress which was compatible with the diagnosis of interstitial lung disease. The nephrotic syndrome was in all cases a laboratory finding and was treated with peritoneal dialysis. Skin blistering started between 2 to 4 months of age and was rather mild. Mucosal membranes were not affected. After trauma, nails became dystrophic. All patients survived the neonatal period but died because of multiorgan failure at 4–19 months of age (100).

### 147.4.3 Rare Subtype: LOC Syndrome

Laryngo–oculo–cutaneous (LOC) syndrome (MIM 245660) is a rare autosomal recessive disorder characterized by cutaneous erosions and granulation tissue in the conjunctival and laryngeal mucosa, without overt skin blistering (58). The condition is confined to the Punjabi Muslim population (59,60). Many patients do not survive childhood, the most common cause of premature death being acute or chronic respiratory obstruction with secondary pulmonary infection and sepsis. Additional symptoms derive from conjunctival granulation tissue which can lead to extensive palpebral occlusion and blindness. Dental deformities are also common. The molecular basis of LOC syndrome is a frame shift mutation in the *LAMA3* gene, which leads to an N-terminal deletion of the  $\alpha 3B$  laminin isoform (59).

### 147.4.4 Dystrophic EB

**147.4.4.1 Dominant DEB.** The clinical spectrum of the dominant DEB (DDEB) (MIM 131750) is broad and can range from localized acral blistering to generalized involvement. Blisters always heal with scarring, and albopapuloid, scar-like lesions on the trunk, prurigo-like nodules on lower legs, nail dystrophy and involvement of the gastrointestinal tract can be features of DDEB (Figure 147-8). IF of the skin shows normal or reduced collagen VII staining at the roof of a trauma-induced blister (61), and TEM shows qualitatively or quantitatively altered anchoring fibrils (62).

**147.4.4.2 Recessive DEB.** Recessive DEB (RDEB) (MIM 226600) can exhibit a broad spectrum of clinical manifestations and degrees of severity (62). It is subdivided into two main subtypes, severe generalized RDEB, and generalized RDEB-other.

Severe generalized RDEB is associated with profound disability, and has a major impact on the quality of life of the patients and their families. Generalized blistering is present at birth and increases progressively, leading to poorly healing wounds and extensive scarring (Figure 147-9A).

Mitten deformities of hands and feet develop early in life (Figure 147-9B, C). Oral and gastrointestinal involvement with blistering, erosions, scarring and strictures leads to malnutrition, which impairs food intake and, in combination with protein loss through the wounds, results in anemia and growth retardation (Figure 147-9D). Squamous cell carcinoma is a feared complication of severe generalized RDEB (63), with a cumulative risk of 70% by the age of 35 years (64). IF of the skin shows absence or significant reduction of collagen VII, and all other marker antibodies map to the blister roof. TEM demonstrates cleavage below the lamina densa and absence or significant reduction of the anchoring fibrils.

The group of RDEB-other comprises a wide range of clinical manifestations, from localized manifestations to generalized blistering of skin and mucous membranes

**FIGURE 147-8** Clinical spectrum of DDEB. (A) Localized DDEB in a 27-year-old man caused by *COL7A1* mutation p.G2064V and manifesting with occasional blisters in areas of mechanical trauma and (B) toenail dystrophy. (C) and (D) Generalized DDEB with nodular and albo-papuloid lesions in a 42-year-old patient with *COL7A1* mutation p.G1755D. Her sister and mother are similarly affected.

**FIGURE 147-9** Clinical features of severe generalized RDEB. (A) Chronic non-healing wounds and scars on skin areas exposed to mechanical trauma on the back of a 30-year-old man with *COL7A1* loss-of-function mutations. (B) and (C) Mitten deformities of hands and feet in severe generalized RDEB. (D) Microstoma and dental caries are common in severe generalized RDEB.

**FIGURE 147-10** Clinical spectrum of RDEB-other. (A) Mild localized disease in a 44-year-old man, homozygous for the *COL7A1* mutation p.G1719R. (B) Generalized RDEB-other in a 56-year-old woman compound heterozygous for *COL7A1* mutations p.R2777X and p.R2069C. Note diffuse scarring alopecia. (C) Blisters and scars on sacral skin areas exposed to mechanical trauma. (D) Palmar scarring, finger contractures and loss of nails in the same patient. Her main complications are related to the esophageal strictures which require yearly dilatation.

(Figure 147-10). Scarring, mucosal involvement, dental and nail dystrophy, or loss of nails are common, however, mitten deformities of hands and feet do not develop. IF of the skin demonstrates a reduced collagen VII signal at the blister roof, and TEM shows reduced number of anchoring fibrils often with altered morphology (61). The molecular bases of all DEB subtypes are mutations in the *COL7A1* gene encoding collagen VII, the major component of the anchoring fibrils. Nonsense mutations are typical in severe generalized RDEB; missense mutations, particularly glycine substitution mutations in the collagenous domain, usually underlie DDEB; the phenotypes in the group of RDEB-other are caused by homozygosity or compound heterozygosity for nonsense, missense and splice site mutations, or small deletions and/or insertions (65,66).

#### 147.4.5 Kindler Syndrome

KS (MIM 173650) is a rare autosomal recessive genodermatosis characterized by congenital skin blistering and mild photosensitivity, which improve with age, and a progressive generalized poikiloderma with extensive skin

atrophy (67). Palmoplantar keratoderma, nail dystrophy, webbing of the fingers and joint contractures may occur (Figure 147-11). Oral, ocular, esophageal, intestinal, anal, urethral, and genital mucous membranes are severely affected in the majority of the patients, leading to impaired quality of life (68,69). Squamous cell carcinoma is a relatively common complication of KS in adults (67,69). IF staining with antibodies to cutaneous basement membrane zone proteins demonstrate discontinuous, branched staining patterns, while TEM reveals reduplication of the basement membrane and different levels of blister formation (see also Figure 147-2C). Mutations in the *KIND1* (*FERMT1*) gene, encoding kindlin-1, cause the KS, with more than 45 different loss-of-function mutations reported to date (69).

#### 147.4.6 Extracutaneous Symptoms and Complications in EB

Extracutaneous symptoms can be associated with EB because the basement membrane zones of the eye, the mucous membranes of the orifices, the gastrointestinal, respiratory and urogenital tracts are similar to the skin. Also the basement membranes in the muscle bear molecular similarities to this zone in the skin. Furthermore, secondary changes, such as scarring and fibrosis can cause symptoms in several organs (Table 147-2) (70). Complications related to skin and mucosal membranes mainly arise in severe EB variants, and may impede the well being and the quality of life (e.g. dysphagia, urethral strictures, pseudosyndactyly), or become life threatening (e.g. systemic infections, skin cancers). These manifestations and the associated EB types are summarized in Table 147-2. Anemia is a frequent feature in severe forms of DEB and JEB. It has a complex pathogenesis and a significant impact on the overall well being of the patients (71). Cardiomyopathy is a rare, or perhaps under-recognized, complication of severe generalized DEB with multifactorial causes, and potentially severe outcome (71).

Rare associations of skin blisters with other organ manifestations have been reported in isolated cases. The association between hereditary nephritis, sensorineural deafness and pretibial epidermolysis bullosa caused by a homozygous single nucleotide insertion in the gene encoding CD151 was described in two sibs (72). Single cases of JEB caused by *LAMB3* and *ITGB4* mutations, respectively, were associated congenital nephrotic syndrome (73,74).

#### 147.5 DIFFERENTIAL DIAGNOSIS

Although EB should be included in the differential diagnosis of a newborn with blisters, the clinical features in a newborn are not characteristic for any subtype (Figure 147-12), and sub-classification on the clinical basis may be difficult even for an experienced pediatrician or dermatologist. Distinct secondary symptoms, such as scarring,

**FIGURE 147-11** Clinical features of KS. (A) Acral skin blistering in a child with KS, homozygous for the *FERMT1* mutation c.676dup. (B) Skin atrophy begins on the dorsal aspects of the hands in childhood and is usually the first cue for the clinical diagnosis. (C) Progressive skin atrophy associated with sclerotic changes on the hand of a 28-year-old man with KS homozygous for the same duplication mutation c.676dup. (D) Webbing of the fingers and pseudoainhum in a 27-year-old man with KS caused by the homozygous *FERMT1* mutation c.1718+1G>A. (E) In children with KS, mild photosensitivity and reticular erythema in sun-exposed areas are common (the same patient as in panel A). (F) Poikiloderma develops in young adults and extends over the entire skin surface (the same patient as in panel C). (G) Gingivitis, periodontitis and cheilitis angularis in a young male with KS caused by the homozygous *FERMT1* mutation c.456dup.

alopecia, nail dystrophy, enamel defects or pigmentary changes, appear later in the course of the disease, which when combined with biopsy data and mutation analysis will then allow appropriate sub-classification.

The differential diagnosis of a newborn must include, apart from all EB types, other genetic skin diseases manifesting with skin erosions or blisters (Table 147-3). In the postnatal period, infections (herpes simplex, staphylococcal infections, candidiasis) should be excluded, as well as blistering due to maternal autoimmune diseases (transplacental antibody transfer in herpes gestationis and pemphigus vulgaris). The differential diagnosis of acquired skin fragility in children and adults is quite broad.

### 147.5.1 Diagnostic Tests

Clinical diagnosis of EB, with sub-classification, is often possible in adults based on the fully developed phenotype, but this may be difficult in a newborn because of the absence of typical secondary symptoms (Figure 147-12) (7). Careful investigation of the family history must be accompanied by a systematic clinical examination of the entire integument and mucosal surfaces, nails, hair and dentition. The involvement of other organs, e.g. digestive, urogenital, or musculoskeletal systems, must also be considered (Table 147-2).

Histopathological analysis of skin biopsies is usually the first diagnostic step. Classical dermatopathology using hematoxylin–eosin staining can distinguish intraepidermal cleavage, but its resolution is not sufficient to distinguish between the junctional and subepidermal tissue separation.

IF mapping is the method of choice for first-line EB diagnostics. This method employs a panel of antibodies against the integral components of the cutaneous basement membrane zone and of the cell–cell contacts as it reveals the level of tissue separation within the blistering areas (Figure 147-2), and can often identify the defective gene due to absent or attenuated staining for the corresponding protein (75). In the majority of cases it is sufficient for the diagnosis of the EB type and may indicate the candidate gene. As a general rule, the degree of the molecular defect correlates with the clinical severity, e.g. complete absence of a cutaneous basement membrane zone protein implies the presence of a severe form of EB. Thus, IF may also be useful for prognostication (76). KS represents a particular challenge, since this condition is characterized by gross abnormalities of the cutaneous basement membrane zone, and multiple components exhibit abnormal staining patterns: collagen XVII,  $\alpha 6\beta 4$  integrins and plectin display interrupted staining patterns at the cutaneous basement membrane zone, whereas

**TABLE 147-2 Main Complications and Extracutaneous Manifestations in EB**

Symptom	Mainly seen in	Comments
Cutaneous complications		
• Infections	All	Sepsis in JEB and lethal congenital EB
• EB nevi	All
